IN THE MANAGEMENT OF ENDOMETRIOSIS

enough is enough

Power to suppress estradiol to levels that result in effective relief

- Lowers serum estradiol to near menopausal levels within approximately 1 month, and maintains those levels throughout the 6-month course of therapy.*
- 92% of patients (n = 143) were symptom-free or had only mild symptoms following a 6-month course of therapy.
- Retreatment cannot be recommended since safety data for retreatment are not currently available.

Control in the management of hypoestrogenic and therapeutic effec

- A small impact on bone,† as well as a predictable and manageable hypoestrogenic profile.
- Lets you terminate treatment immediately should that be required for any reason, unlike the depot form of GnRH‡ therapy.

*Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a nonhormonal method of contraception when taking SYNAREL.
†There is a small loss in bone density with 6-month treatment, some of which may not be reversible. During one treatment period the bone loss should not be important. ‡Gonadotropin-releasing hormone analog. Please see brief summary of prescribing information on next page.

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS General: Ovarian cysts have been reported in the first 2 months of therapy. These may resolve spontaneously or may require drug discontinuation or surgery.

Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. If patient is compliant and menstruation persists to second month, consider doubling the dose. Counsel noncompliant patients on importance of taking SYNAREL regularly. 2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients. 3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician. 4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients. 5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content. 6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption. 7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

Genetics is much more than child's play.
A lot of companies offer laboratory tests. But it's not easy to find one with our focused experience in genetics and infertility. At the Genetics & IVF Institute, we understand the needs of obstetricians because we're one of you. In our well-respected national reference laboratories, your patients' samples get the same attention and turnaround time as our own. In prenatal cytogenetics, you benefit from rapid amniocentesis and one of the world's most experienced chorionic villus (CVS) labs. We offer you expertise in Fragile X testing, molecular DNA analysis for disease/carrier detection and paternity testing, blood chromosome analysis, and MSAFP and AFP+ screening. For treatment of infertility, you can obtain top quality, genetically screened donor semen from the Fairfax Cryobank, and order rapid hormone assays 365 days a year. And if you ever need help with a test result, you consult directly with our laboratory heads, M.D.s, and counselors.
GENETICS & IVF INSTITUTE

CEFOTAN® IM/IV
(cefotetan disodium)
Available in 1-gram and 2-gram vials

For Intravenous or Intramuscular Use
PLEASE SEE FULL PRESCRIBING INFORMATION FOR A COMPLETE DESCRIPTION.
A BRIEF SUMMARY FOLLOWS.

INDICATIONS AND USAGE
TREATMENT

CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary Tract Infections caused by *E. coli, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis*, and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri*, and *Morganella morganii*).

Lower Respiratory Tract Infections caused by *Streptococcus pneumoniae* (formerly *D. pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K. pneumoniae*), *E. coli, Proteus mirabilis*, and *Serratia marcescens**.

Skin and Skin Structure Infections due to *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes, Streptococcus* species (excluding enterococci), *Escherichia coli, Klebsiella pneumoniae, Peptococcus niger**, *Peptostreptococcus* species.

Gynecologic Infections caused by *Staphylococcus aureus* (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *Streptococcus agalactiae, E. coli, Proteus mirabilis, Neisseria gonorrhoeae,* Bacteroides species (excluding *B. distasonis, B. ovatus, B. thetaiotaomicron*), *Fusobacterium* species*, and gram-positive anaerobic cocci (including *Peptococcus niger* and *Peptostreptococcus* species).

Cefotetan, like other cephalosporins, has no activity against *Chlamydia trachomatis*. Therefore, when cephalosporins are used in the treatment of pelvic inflammatory disease, and *C. trachomatis* is one of the suspected pathogens, appropriate antichlamydial coverage should be added.

Intra-abdominal Infections caused by *E. coli, Klebsiella* species (including *K. pneumoniae*), *Streptococcus* species (excluding enterococci), *Bacteroides* species (excluding *B. distasonis, B. ovatus, B. thetaiotaomicron*) and *Clostridium* species*.

Bone and Joint Infections caused by *Staphylococcus aureus**.

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic *in vitro* against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

PROPHYLAXIS

The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (e.g., cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

BEFORE THERAPY WITH CEFOTAN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOTETAN DISODIUM, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. IF THIS PRODUCT IS TO BE GIVEN TO PENICILLIN-SENSITIVE PATIENTS, CAUTION SHOULD BE EXERCISED BECAUSE CROSS-HYPERSENSITIVITY AMONG BETA-LACTAM ANTIBIOTICS HAS BEEN CLEARLY DOCUMENTED AND MAY OCCUR IN UP TO 10% OF PATIENTS WITH A HISTORY OF PENICILLIN ALLERGY. IF AN ALLERGIC REACTION TO CEFOTAN OCCURS, DISCONTINUE THE DRUG. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE TREATMENT WITH EPINEPHRINE AND OTHER EMERGENCY MEASURES, INCLUDING OXYGEN, INTRAVENOUS FLUIDS, INTRAVENOUS ANTIHISTAMINES, CORTICOSTEROIDS, PRESSOR AMINES AND AIRWAY MANAGEMENT, AS CLINICALLY INDICATED.

Pseudomembranous colitis has been reported with nearly all antibacterial agents, including cefotetan, and may range from mild to life-threatening. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment or surgical prophylaxis. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is a primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to discontinuation of the drug alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *Clostridium difficile*.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated.

PRECAUTIONS

General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

Drug/Laboratory Test Interactions: The administration of CEFOTAN may result in a false-positive reaction for glucose in the urine using Clinitest®†, Benedict's solution, or Fehling's solution. It is recommended that glucose tests based on enzymatic glucose oxidase be used.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

Pregnancy: Teratogenic Effects. Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies, the following adverse effects were considered related to CEFOTAN therapy. Those appearing in italics have been reported during postmarketing experience.

Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700); *pseudomembranous colitis*. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment or surgical prophylaxis. (See WARNINGS.)

Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300); *agranulocytosis, hemolytic anemia, leukopenia, thrombocytopenia,* and *prolonged prothrombin time*.

Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700); *anaphylactic reactions*.

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

Miscellaneous: *Fever*

In addition to the adverse reactions listed above which have been observed in patients treated with cefotetan, the following adverse reactions and altered laboratory tests have been reported for cephalosporin-class antibiotics: urticaria, pruritis, Stevens-Johnson syndrome, erythema multiforme, toxic epidermal necrolysis, vomiting, abdominal pain, colitis, superinfection, vaginitis including vaginal candidiasis, renal dysfunction, toxic nephropathy, hepatic dysfunction including cholestasis, aplastic anemia, hemorrhage, increased BUN, increased creatinine, elevated bilirubin, pancytopenia, and neutropenia.

Several cephalosporins have been implicated in triggering seizures, particularly in patients with renal impairment when the dosage was not reduced (see DOSAGE AND ADMINISTRATION and OVERDOSAGE). If seizures associated with drug therapy occur, the drug should be discontinued. Anticonvulsant therapy can be given if clinically indicated.

DOSAGE AND ADMINISTRATION
TREATMENT

The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Skin & Skin Structure		
Mild-Moderate[a]	2 grams	2 g every 24 hours IV 1 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6 grams[b]	3 g every 12 hours IV

[a] *K. pneumoniae* skin and skin structure infections should be treated with 1 or 2 grams every 12 hours IV or IM.

[b] Maximum daily dosage should not exceed 6 grams.

If *C. trachomatis* is a suspected pathogen in gynecologic infections, appropriate antichlamydial coverage should be added, since cefotetan has no activity against this organism.

PROPHYLAXIS

To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION

When renal function is impaired, a reduced dosage schedule must be employed. See FULL PRESCRIBING INFORMATION for a complete description.

NOTE: Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Hospitalization for pregnancy complications, United States, 1986 and 1987 1339
Adele L. Franks, MD, Juliette S. Kendrick, MD, David R. Olson, PhD, Hani K. Atrash, MD, MPH, Audrey F. Saftlas, PhD, MPH, and Mary Moien, MS
Atlanta, Georgia

Demographic features and magnitude of the problem of inpatient care for pregnancy complications were investigated with a nationally representative sample of hospitalizations.

Buserelin acetate versus expectant management in the treatment of infertility associated with minimal or mild endometriosis: A randomized clinical trial 1345
Luigi Fedele, MD, Fabio Parazzini, MD, Enrico Radici, MD, Luca Bocciolone, MD, Stefano Bianchi, MD, Cosetta Bianchi, ScD, and Giovanni Battista Candiani, MD
Milan and Bergamo, Italy

The efficacy of intranasal buserelin versus expectant management in the treatment of infertile women with stage I and II endometriosis has been analyzed in a randomized clinical trial: The 1-year and 2-year overall pregnancy rates were similar in the two groups.

Magnetic cell sorting and the transferrin receptor as potential means of prenatal diagnosis from maternal blood 1350
Dorothee Gänshirt-Ahlert, PhD, Monika Burschyk, MS, Henk S.P. Garritsen, MD, Lisa Helmer, BS, Peter Miny, MD, Jürgen Horst, MD, Hermann P.G. Schneider, MD, and Wolfgang Holzgreve, MD
Münster, Germany

Although magnetic-activated cell sorting was shown to be an effective enrichment method in a test model, the transferrin receptor antibody was proved not to be specific enough for the isolation of fetal nucleated erythrocytes from maternal blood.

Training obstetric and family practice residents to give smoking cessation advice during prenatal care 1356
Roger H. Secker-Walker, MB, BChir, Laura J. Solomon, PhD, Brian S. Flynn, ScD, Sandy S. LePage, RN, Jane E. Crammond, RN, John K. Worden, PhD, and Philip B. Mead, MD
Burlington, Vermont

Obstetric and family practice residents were successfully trained to provide smoking cessation advice consistently to pregnant smokers.

Impact of histocompatibility antigens on pregnancy outcome 1364
Gungor Eroglu, MD, George Betz, MD, and Caprice Torregano, BS
New Orleans, Louisiana, and Denver, Colorado

Histocompatibility antigens neither have an impact on the outcome of pregnancy nor play a role in the etiology of idiopathic recurrent spontaneous abortion.

Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy 1369
Donald M. Peebles, MB, BS, A. David Edwards, MB, John S. Wyatt, MB, Anthony P. Bishop, Mark Cope, PhD, David T. Delpy, DSc, and E. Osmund R. Reynolds, MD
London, England

Near-infrared spectroscopy provides continuous information about cerebral oxygenation and blood volume and shows that fetal heart rate decelerations are associated with transient cerebral desaturation.

Risk factors for small-for-gestational-age birth in a preterm population 1374
Janet M. Lang, PhD, ScD, Amy Cohen, AB, and Ellice Lieberman, MD, DrPH
Boston, Massachusetts

Maternal risk factors for small-for-gestational-age birth among premature infants were black race, toxemia, and low weight gain or unavailable data on weight gain.

Treatment of unruptured tubal pregnancy by laparoscopic instillation of hyperosmolar glucose solution 1378
Peter F. Lang, MD, Karl Tamussino, MD, Werner Hönigl, MD, and George Ralph, MD
Graz, Austria

Laparoscopic instillation of hyperosmolar glucose into unruptured tubal pregnancies seems safe and effective when the serum level of human chorionic gonadotropin is $\leq$2500 mU/ml.

The relationship between acute inflammatory lesions of the preterm placenta and amniotic fluid microbiology 1382
Roberto Romero, MD, Carolyn M. Salafia, MD, Apostolos P. Athanassiadis, MD, Shuichi Hanaoka, MD, Moshe Mazor, MD, Waldo Sepulveda, MD, and Michael B. Bracken, PhD
New Haven and Danbury, Connecticut, and Detroit, Michigan

The presence of acute inflammatory lesions of the chorioamniotic membranes (chorioamnionitis) can serve as a marker of microbial invasion of the amniotic cavity.

Maternal serum α-fetoprotein, β-human chorionic gonadotropin, and unconjugated estriol levels in midtrimester trisomy 18 pregnancies 1388
Frank Greenberg, MD, Deborah Schmidt, RN, Asha T. Darnule, MD, PhD, Barbara R. Weyland, MPH, Esmie Rose, PhD, and Elliot Alpert, MD
Houston, Texas

Maternal serum levels of α-fetoprotein and β-human chorionic gonadotropin may show a bimodal distribution in trisomy 18 pregnancies that may affect screening efficiency.

Ultrastructure of the microvasculature in the human endometrium throughout the normal menstrual cycle 1393
Daniel K. Roberts, MD, PhD, Tim H. Parmley, MD, Nola J. Walker, EMSA, and Douglas V. Horbelt, MD
Wichita, Kansas, and Little Rock, Arkansas

Ultrastructural morphologic features of endothelial cells in human endometrial capillaries reveal cyclic development; direct cell-to-cell contact may be a possible requirement for coordinated growth and development.

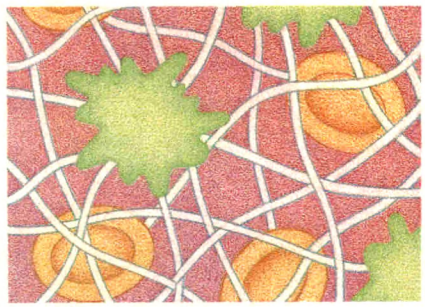
NEW from MedChem Products

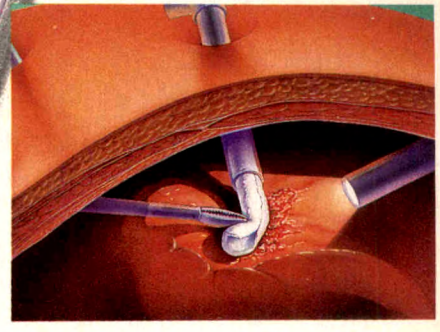


Endo-Avitene™

Microfibrillar Collagen Hemostat in an Endoscopic Delivery System.

Avitene® Microfibrillar Collagen Hemostat (MCH) is now packaged ready for use in a unique delivery system designed for endoscopic procedures. This 100% collagen topical hemostat:

- eliminates risk of thermal damage.
- adheres tenaciously to the bleeding site.
- allows for the easy removal of excess by irrigation and suction.
- is effective in controlling delayed bleeding.
- is absorbable.



The Endo-Avitene device makes delivery and application of Avitene MCH to the bleeding site easy. Simply insert the delivery system through a 10 mm trocar sheath and deliver Avitene MCH directly to the bleeding site. Avitene MCH is positioned using a unique blunt plunger tip that can be used to apply pressure during placement.

MCH potentiates the clotting mechanism by attracting platelets.

We control bleeding. We reduce risk. And we deliver.

Contact us to arrange a demonstration. We'll supply the Endo-Avitene device free of charge. Call us today, and we'll deliver: 1-800-451-4716 (in Massachusetts, 617- 938-9328).

Endo-Avitene, for use in endoscopic procedures.

Chorionic villus sampling for fetal Rh typing: Clinical implications 1407
T.S. Kickler, MD, K. Blakemore, MD, R.S. Shirey MS, S. Nicol, BS, N. Callan, MD, P.M. Ness, MD, C. Escallon, MS, and G. Dover, MD
Baltimore, Maryland

A simple technique is described for Rh phenotyping of fetal red blood cells from chorionic villus samples at 9 to 11 weeks' gestation.

Infertility and pregnancy outcome in an unselected group of women with insulin-dependent diabetes mellitus 1412
Karen Kjaer, MD, Claus Hagen, MD, Steen H. Sandø, MD, and Ole Eshøj, MD
Odense, Denmark

Fertility in diabetic women is normal, but diabetic women have fewer pregnancies and fewer births per pregnancy than nondiabetic women; only half of pregnancies in diabetic women are planned.

Effects of mefenamic acid on menstrual hemostasis in essential menorrhagia 1419
Marion A. van Eijkeren, MD, PhD, Godelieve C.M.L. Christiaens, MD, PhD, Hans J. Geuze, MD, PhD, Ary A. Haspels, MD, PhD, and Jan J. Sixma, MD, PhD
Utrecht, The Netherlands

Mefenamic acid improves menstrual hemostasis in essential menorrhagia through an improvement of platelet aggregation and degranulation and through increased vasoconstriction.

Elevated plasma Met-enkephalin levels in the human newborn are a poor indicator of perinatal stress 1429
Alma M. Martinez, MD, James F. Padbury, MD, Leslie M. Barberie, BS, Elizabeth E. Burnell, BS, and Siang Thio, BS
Los Angeles and Torrance, California

Although elevated in umbilical cord plasma of newborn infants after labor, circulating plasma Met-enkephalin levels correlate poorly with markers of perinatal stress.

Lack of reactivity of uterine arteries from patients with obstetric hemorrhage 1436
Sharon H. Nelson, PhD, and Maya S. Suresh, MD
Galveston, Texas

Isolated uterine arteries from patients with obstetric hemorrhage had depressed reactivity to vasoconstrictors; the depression was not mediated by vasodilator prostaglandins, endothelium-derived relaxing factor, or elevated adenosine 3′:5′-cyclic monophosphate.

Contraception PLUS health benefits for the woman over 35

Because she needs an effective contraceptive that may provide specific noncontraceptive health benefits.*

TRI-LEVLEN®

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

ENHANCING YOUR PERCEPTION OF ORAL CONTRACEPTION

*Serious as well as minor side effects have been reported with use of all oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

BERLEX Dedicated to innovation in OB/GYN medicine

914300071

TRI·LEVLEN® Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen

TRI-LEVLEN® 28 TRI-LEVLEN® 21

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use this product as a method of contraception.

Contraindications

Oral contraceptives should not be used in women with any of the following conditions: thrombophlebitis or thromboembolic disorders, a past history of deep-vein thrombophlebitis or thromboembolic disorders, cerebral-vascular or coronary-artery disease, known or suspected carcinoma of the breast, carcinoma of the endometrium or other known or suspected estrogen-dependant neoplasia, undiagnosed abnormal genital bleeding, cholestatic jaundice of pregnancy or jaundice with prior pill use, hepatic adenomas or carcinomas, known or suspected pregnancy.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, gallbladder disease, and hypertension, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long-term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of disease, namely, a ratio of the incidence of a disease among oral-contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the difference in the incidence of disease between oral-contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods.

1. *Thromboembolic Disorders and Other Vascular Problems*

a. *Myocardial Infarction.* An increased risk of myocardial infarction has been attributed to oral-contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral-contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral-contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in "Warnings"). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. *Thromboembolism.* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to nonusers to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep-vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped. A two-to four-fold increase in relative risk of postoperative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate post partum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four to six weeks after delivery in women who elect not to breast-feed, or a midtrimester pregnancy termination.

c. *Cerebrovascular diseases.* Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and nonusers, for both types of strokes, while smoking interacted to increase the risk for hemorrhagic strokes. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women.

d. *Dose-related risk of vascular disease from oral contraceptives.* A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high-density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high-density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogen used in the contraceptive. The amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral-contraceptive agents should be started on preparations containing less than 50 mcg of estrogen.

e. *Persistence of risk of vascular disease.* There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral-contraceptive formulations containing 50 micrograms or higher of estrogens.

2. *Estimates of Mortality from Contraceptive Use.* One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral-contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral-contraceptive users is based on data gathered in the 1970's–but not reported until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral-contraceptive use to women who do not have the various risk factors listed in this labeling. Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with oral-contraceptive use after age 40 in healthy nonsmoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception. Therefore, the Committee recommended that the benefits of oral-contraceptive use by healthy nonsmoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. *Carcinoma of the Reproductive Organs.* Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The overwhelming evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and nonusers and differences in age at start of use, has been questioned. Some studies suggest that oral-contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral-contraceptive use and breast and cervical cancers, a cause-and-effect relationship has not been established.

4. *Hepatic Neoplasia.* Benign hepatic adenomas are associated with oral-contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral-contraceptive users. However, these cancers are extremely rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral-contraceptive users approaches less than one per million users.

5. *Ocular Lesions.* There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. *Oral-Contraceptive Use Before or During Early Pregnancy.* Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. Studies also do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb-reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing oral-contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral-contraceptive use should be discontinued if pregnancy is confirmed.

7. *Gallbladder Disease.* Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral-contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral-contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. *Carbohydrate and Lipid Metabolic Effects.* Oral contraceptives have been shown to cause glucose intolerance in a significant percentage of users. Oral contraceptives containing greater than 75 micrograms of estrogens cause hyperinsulinism, while lower doses of estrogen cause less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the nondiabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see "Warnings" 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral-contraceptive users.

9. *Elevated Blood Pressure.* An increase in blood pressure has been reported in women taking oral contraceptives and this increase is more likely in older oral-contraceptive users and with continued use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing quantities of progestogens. Women with a history of hypertension or hypertension-related diseases, or renal disease should be encouraged to use another method of contraception. If women with hypertension elect to use oral contraceptives, they should be monitored closely, and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension among ever-and never-users.

10. *Headache.* The onset or exacerbation of migraine or development of headache with a new pattern that is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. *Bleeding Irregularities.* Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. The type and dose of progestogen may be important. Nonhormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent.

Precautions

1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. (See "Warnings" 1d.) 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine-and liver-function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral-contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See "Warnings" section. 10. PREGNANCY. Pregnancy Category X. See "Contraindications" and "Warnings" sections. 11. NURSING MOTHERS. Small amounts of oral-contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

Information for the Patient

See Patient Labeling.

Adverse Reactions

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see "Warnings" section): thrombophlebitis, arterial thromboembolism, pulmonary embolism, myocardial infarction, cerebral hemorrhage, cerebral thrombosis, hypertension, gallbladder disease, hepatic adenomas or benign liver tumors.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: mesenteric thrombosis, retinal thrombosis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: nausea; vomiting; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; temporary infertility after discontinuation of treatment; edema; melasma which may persist; breast changes: tenderness, enlargement, secretion; change in weight (increase or decrease); change in cervical erosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: congenital anomalies, premenstrual syndrome, cataracts, optic neuritis, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, cerebral-vascular disease with mitral valve prolapse, lupus-like syndromes, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function, hemolytic uremic syndrome, Budd-Chiari syndrome, acne, changes in libido, colitis, sickle-cell disease.

Overdosage

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits

The following noncontraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral-contraceptive formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: increased menstrual cycle regularity, decreased blood loss and decreased incidence of iron-deficiency anemia, decreased incidence of dysmenorrhea.

Effects related to inhibition of ovulation: decreased incidence of functional ovarian cysts, decreased incidence of ectopic pregnancies.

Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence of acute pelvic inflammatory disease, decreased incidence of endometrial cancer, decreased incidence of ovarian cancer.

Dosage and Administration

To achieve maximum contraceptive effectiveness, TRI-LEVLEN® tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours.

For full details on dosage and administration see prescribing information in package insert. 60627-0 5/90

A reevaluation of estrogen status in postmenopausal women who smoke 1444
Denise Lee Cassidenti, MD, Malcolm C. Pike, PhD, Ariel G. Vijod, MS, Frank Z. Stanczyk, PhD, and Rogerio A. Lobo, MD
Los Angeles, California

Smoking increases adrenal activity, resulting in higher androstenedione levels, but in nonusers of estrogen smoking does not appear to be associated with changes in estrogen levels.

Human fetal bilirubin levels and fetal hemolytic disease 1449
Carl P. Weiner, MD
Iowa City, Iowa

An elevated fetal bilirubin level identifies the antigen-positive fetus as high risk for the development of alloimmune hemolytic anemia.

Origin of cervical collagenase during parturition 1455
R. Osmers, MD, B.C. Adelmann-Grill, MD, PhD, C. Fittkow, MD, M. Kuloczik, MD, M. Szeverényi, MD, H. Tschesche, PhD, and W. Kuhn, MD
Göttingen, Martinsried, Munich, and Bielefeld, Germany, and Debrecen, Hungary

Collagenase activity observed in cervical tissue during parturition is probably derived from invading polymorphonuclear leukocytes and not from resident fibroblasts.

Acute genital injury in the prepubertal girl 1461
Susan F. Pokorny, MD, William J. Pokorny, MD, and Wayne Kramer, MD
Houston, Texas

Guidelines for management of genital injuries in the prepubertal girl are needed to minimize the physical and psychosocial trauma of the survivor.

The use of a neural network for the ultrasonographic estimation of fetal weight in the macrosomic fetus 1467
Richard M. Farmer, MD, PhD, Arnold L. Medearis, MD, Greigh I. Hirata, MD, and Lawrence D. Platt, MD
Los Angeles, California

Results obtained from a biologically simulated intelligence model, or neural network, in the estimation of fetal weight in the clinically suspected macrosomic fetus are compared with previously published formulas; the neural network performed statistically better.

Fetal echocardiography: Accuracy and limitations in a population at high and low risk for heart defects 1473
Bryann Bromley, MD, Judy A. Estroff, MD, Stephen P. Sanders, MD, Richard Parad, MD, Drucilla Roberts, MD, Fredric D. Frigoletto, Jr., MD, and Beryl R. Benacerraf, MD
Boston, Massachusetts

Fetal echocardiography accurately identifies 83% of fetuses with heart defects in both high- and low-risk populations.

In situ and invasive vulvar cancer incidence trends (1973 to 1987) 1482
Susan R. Sturgeon, DrPH, Louise A. Brinton, PhD, Susan S. Devesa, PhD, and Robert J. Kurman, MD
Bethesda and Baltimore, Maryland

In situ vulvar carcinoma incidence nearly doubled from the period 1973 through 1976 to the period 1985 through 1987; invasive squamous cell carcinoma incidence was relatively stable over the same period.

Comprehensive fetal assessment with three ultrasonographic characteristics 1486
David K. James, MD, Michael J. Parker, MD, and John S. Smoleniec, MB
Bristol, England

Useful prediction of outcome was obtained by fetal assessment combining umbilical artery Doppler recording with abdominal circumference measurement and with the biophysical profile score.

A model-based prediction for transvaginal ultrasonographic identification of early intrauterine pregnancy 1495
Bruce S. Shapiro, MD, Michael Escobar, PhD, Robert Makuch, PhD, Gad Lavy, MD, and Alan H. DeCherney, MD
New Haven, Connecticut

A mathematic model for transvaginal ultrasonographic detection of early intrauterine pregnancy was constructed, predicting identification by human chorionic gonadotropin titer or gestational age.

Influence of labor and oxytocin on in vitro leukotriene release by human fetal membranes and uterine decidua at term gestation 1500
Nino Pasetto, MD, Alessandra Zicari, MD, Emilio Piccione, MD, Luisa Lenti, MD, Giuseppe Pontieri, MD, and Carlo Ticconi, MD
Rome, Italy

The in vitro leukotriene release by human fetal membranes and uterine decidua in response to calcium ionophore is higher after the onset of labor and is enhanced by oxytocin.

Comparison of adenocarcinoma and squamous cell carcinoma of the uterine cervix: A population-based epidemiologic study 1507
Hoda Anton-Culver, PhD, Jeffrey D. Bloss, MD, Deborah Bringman, MPH, Anna Lee-Feldstein, PhD, Philip DiSaia, MD, and Alberto Manetta, MD
Irvine, California

Cervical adenocarcinoma was diagnosed at a younger age and an earlier stage than squamous cell carcinoma; risk for squamous cell carcinoma was highest in Hispanics and for adenocarcinoma in Asians.

Contents

Current Development

A review of premature birth and subclinical infection 1515
R.S. Gibbs, MD, R. Romero, MD, S.L. Hillier, PhD, D.A. Eschenbach, MD, and R.L. Sweet, MD
Denver, Colorado, Detroit, Michigan, Seattle, Washington, and San Francisco, California

This article reviews evidence suggesting a link between subclinical infection and prematurity.

BASIC SCIENCE SECTION

In the rhesus monkey placental retention after fetectomy at 121 to 130 days' gestation outlasts the normal duration of pregnancy 1529
P.W. Nathanielsz, MD, PhD, J.P. Figueroa, MD, PhD, and M.B.O.M. Honnebier, MD
Ithaca, New York

After removal of the fetus at 121 to 130 days' gestation, the placenta of the pregnant rhesus monkey is retained in utero past the normal duration of pregnancy.

The effect of benzo(a)pyrene on murine ovarian and corpora lutea volumes 1535
Michael M. Miller, MD, David R. Plowchalk, PhD, Glenn A. Weitzman, MD, Steve N. London, MD, and Donald R. Mattison, MD
Little Rock and Jefferson, Arkansas, Durham, North Carolina, Lexington, Kentucky, and Pittsburgh, Pennsylvania

Intraperitoneal injection of the polycyclic aromatic hydrocarbon benzo(a)pyrene produced a time- and dose-dependent decrease in ovarian volume, total corpora luteal volume, and number of corpora lutea per ovary.

The mechanisms of preterm labor: Common genital tract pathogens do not metabolize arachidonic acid to prostaglandins or to other eicosanoids 1541
Phillip R. Bennett, BSc, MD, and Murdoch G. Elder, MD
London, England

With radiolabeled arachidonic acid and high-performance liquid chromatography it was demonstrated that, although they do take up arachidonic acid, common genital tract pathogens cannot synthesize either prostaglandins or other eicosanoids and therefore cannot initiate preterm labor by direct release of these compounds.

Renal autoregulation in midterm and late-pregnant rats 1546
Jane F. Reckelhoff, PhD, Stanley D. Yokota, PhD, and Christine Baylis, PhD
Morgantown, West Virginia

Autoregulation of renal blood flow remains intact in the gravid rat in spite of midterm renal vasodilatation and late gestational hypotension.

Effects of antenatal thyrotropin-releasing hormone, antenatal corticosteroids, and postnatal ventilation on surfactant mobilization in premature rabbits 1551
Steven Seidner, MD, Evelyn Rider, MD, Alan Jobe, MD, PhD, Takako Yamada, MD, and Machiko Ikegami, MD, PhD
Torrance, California

Mobilization of surfactant in premature rabbits was not affected by antenatal thyrotropin-releasing hormone or corticosteroids, but the mode of ventilation used postnatally had significant effects.

Nω-Nitro-L-arginine, an inhibitor of nitric oxide synthesis, increases blood pressure in rats and reverses the pregnancy-induced refractoriness to vasopressor agents 1560
Miklós Molnár, MD, and Frank Hertelendy, PhD, DSc
St. Louis, Missouri

Experimental evidence indicates that nitric oxide is an important regulator of pregnancy-associated vasodilatation and reduced pressor responsiveness.

Role of prostaglandins in the metabolic responses of the fetus to hypoxia 1568
Stuart B. Hooper, PhD, Richard Harding, PhD, Jan Deayton, BSc, and Geoffrey D. Thorburn, MD
Clayton, Victoria, Australia

Inhibiting prostaglandin synthesis during fetal hypoxia increases the severity of the hyperglycemia, acidemia, and hyperlactemia that are normally associated with hypoxia.

Tumor necrosis factor in preterm and term labor 1576
Roberto Romero, MD, Moshe Mazor, MD, Waldo Sepulveda, MD, Cecilia Avila, MD, Diane Copeland, MS, and John Williams, PhD
New Haven, Connecticut, Detroit, Michigan, and Cambridge, Massachusetts

Amniotic fluid tumor necrosis factor-α concentrations are elevated in women with preterm labor and microbial invasion of the amniotic cavity and in women with spontaneous term labor.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318 USA; phone (314) 453-4394. In the U.S., call toll-free: 1-800-325-4177, ext. 4394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Authorization to photocopy items for internal or personal use is granted by Mosby–Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. You think it's good medicine. She thinks it's wonderful.

Thanks to you and Premarin®, she could make these years the best years of her life

Hot flashes–Now part of the past for millions of women

Premarin® can dramatically reduce the incidence of hot flashes, night sweats, and related sleep disturbances.

Osteoporosis–No longer part of the future for many women

Premarin® is the first estrogen product proven to prevent postmenopausal osteoporosis in women at risk. And it's the *only* estrogen product proven in studies to reduce the risk of osteoporosis-related fractures by as much as 62%.[1]

Contraindications

Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogen-dependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

Note: Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women.

Nothing else is

PREMARIN®

(conjugated estrogens tablets)

The appearance of this tablet is a trademark of Wyeth-Ayerst Laboratories.

Please see brief summary of prescribing information on next page.

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.
There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risks, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATIONS** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy: changes in vaginal bleeding pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breasts; nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:
PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atrophic vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.
Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 days followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.
Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

Revised August 21, 1989

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors (N Engl J Med 1991;324:424-8). Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern and southeastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. J. Peter Van Dorsten, P.O. Box 34, MCV Station, Richmond, VA 23298.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's suggested reviewers. When authors submit their manuscripts, they must provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. If not completed in full, it will be returned to the author for completion. The copyright statement and checklist form may be torn from the JOURNAL or photocopied for submission.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) or some of the same authors has been previously published in any medium that deals in any respect whatsoever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article(s) or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. Two copies of a new manuscript being prepared for possible publication also must be submitted. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and nonhuman experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the

requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the *Material and Methods* section of the submitted manuscript. Reports of experiments on nonhuman animals or other species must *state in the* Material and Methods *section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The type of nonhuman animals or other species used in an investigation must be named in the title, abstract, key words, and *Material and Methods* section of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. *In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.*

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of black-and-white glossy prints of illustrations are required. See "Color figures" and "Computer-generated figures" for special requirements. Manuscripts must be submitted in English.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. *At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).*

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page including key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Below the abstract, list 3 to 5 *key words or short phrases* for indexing purposes.

A structured abstract is required for certain types of articles and a *standard abstract format* is required for other types of articles; therefore the author(s) should select and prepare the appropriate abstract to be used in the submitted manuscript. This applies to both independently submitted and society manuscripts.

Structured abstract. A structured abstract, limited to 150 words, is to be used for regular articles, society articles, and Current Investigation articles; excluded are Clinical Opinion, Current Development, case report, and brief communication articles. The structured abstract is to contain the following major headings: *Objective(s); Study Design; Results;* and *Conclusion(s).* The *Objective(s)* reflects the purpose of the study, that is, the hypothesis that is being tested. The *Study Design* should include the setting for the study, the subjects (number and type), the treatment or intervention, and the type of statistical analysis. The *Results* include the outcome of the study and statistical significance if appropriate. The *Conclusion(s)* states the significance of the results.

Standard abstract. The standard abstract format is required for Clinical Opinion, Current Development, case report, and brief communication articles. The standard abstracts for Clinical Opinion and Current Development articles are to be 50 to 150 words and standard abstracts for case reports and brief communications are limited to 50 words. Even though the formal names of these four types of articles are not used, an author should determine his/her type of manuscript and prepare the appropriate standard abstract, regardless of whether it is to be submitted independently or as a part of a society's transactions.

Text. Do not hesitate to write your manuscript in the first person and active voice if they are more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through *Comment* section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

Council of Biology Editors Style Manual or the AMA's *Manual of Style.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify *Material and Methods*, *Results*, and *Comment.* Authors may wish to summarize their findings in a short paragraph at the end of the *Comment* section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to repeat the study) the plan, the patients, experimental animals or other species, material, and controls, the methods and procedures utilized, and the statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the *Comment* section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the *Results* section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (N Engl J Med 1991;324:424-8). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. *This signed permission must accompany the manuscript when it is submitted to the Editor.* Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page if the color balance is appropriate.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures.The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed together in numeric order double-spaced on one sheet of paper (or more if necessary) separate from the text of the manuscript. This page must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from *the copyright owner and original author* along with complete reference information. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for certain types of manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include *standard abstract format*, of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article. The abstract *must* follow the *structured format.*

Clinical Opinion. Limit of 3000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. *Letters to the Editors* must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name[s] and address[es] of the signer[s], and the phrase "To the Editors"). The submitted *Letter to the Editors* must be accompanied by a signed copyright statement. If there are two or more signers of the *Letter to the Editors,* one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all cosigners." These requirements apply to all types of *Letters to the Editors.* Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A *Letter to the Editors* commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a *Letter to the Editors* will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (1-800-325-4177, ext. 4306, or 314-453-4306).

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The completed checklist is enclosed. The assignment of copyright signed by **all** authors accompanies the manuscript.
—Human experimentation has been approved by the local institution as stated in the *Material and Methods* section.
—Guidelines for the care and use of *nonhuman* animals or *other species* approved by the institution have been followed as indicated in the *Material and Methods* section. *The species is named in the title, abstract, key words, and* Material and Methods *section.*
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed in English double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, structured or standard abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any coauthors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author and/or some of the coauthors have previously published, have submitted for possible publication, or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities, differences and explanation are provided in the covering letter that accompanies the submitted manuscript.

Reviewers

—Names and addresses of three suggested reviewers are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title.
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than United States in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the institutional affiliation(s) of the author(s) at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract and key words or short phrases

—The abstract (structured or standard format) is typed double-spaced with required margins on page 3 headed by the title and author(s) name(s). Beneath the abstract 3 to 5 key words or short phrases are typed.
—A *structured abstract,* with 150 words or less, is submitted as required for regular articles, society regular-type articles, and Current Investigation articles. The abstract contains the four required major headings: Objective(s), Study Design, Results, and Conclusion(s), each with a brief adequate presentation.
—A *standard abstract* is submitted as required for Clinical Opinion and Current Development articles with 50 to 150 words and for case reports and brief communications articles with a maximum of 50 words, be they independent or society articles.

References

—Are typed double-spaced.
—Are numbered consecutively in the order they are cited in the text.
—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors have been followed.
—Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Figures

—Each is numbered with an Arabic numeral and cited in numeric sequence in the text.
—Three sets of unmounted glossy prints for *black-and-white* figures are submitted, properly numbered, labeled, and *top indicated* on the back of each print.
—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back and *top indicated* are submitted. None are dot matrix or photographic prints.
—Original transparencies of *color photographs* appropriately numbered and identified and *top indicated* are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

Figure legends

—Are provided for each figure.
—Are numbered and typed together in numeric order on one sheet of paper (more if necessary). The page is numbered in sequence after the References page(s).

Tables

—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in numeric sequence in the text.

Resident attrition in obstetrics and gynecology

Vicki L. Seltzer, MD,[a] Robert H. Messer, MD,[b] and R. DeAnne Nehra[c]

Jamaica, New York, Lubbock, Texas, and Washington, D.C.

OBJECTIVE: Our goal was to determine the rate of attrition from obstetrics and gynecology residency programs.

STUDY DESIGN: The Council on Resident Education in Obstetrics and Gynecology sent questionnaires to all 295 obstetrics and gynecology residency program directors in the United States and Canada. These programs represent 4306 postgraduate-year 1 through 4 (or 5) resident positions each year. The program directors were asked the number of residents who left voluntarily or were dismissed in a 2-year period and the reasons they left.

RESULTS: In a 2-year period 299 residents left or were dismissed (6.94% over 2 years, or 3.47% per year). Only 88 (1% per year) left specifically because they decided they preferred a different discipline.

CONCLUSION: The rate of attrition from obstetrics and gynecology residency programs is not excessively high. (AM J OBSTET GYNECOL 1992;166:1315-7.)

Key words: Resident education, resident dismissal, resident attrition

In the 1990 National Residents' Matching Program, obstetrics and gynecology was the most popular of the six major specialties. The Program filled 86% of the obstetrics and gynecology positions with U.S. medical school seniors on the first round of the match, compared with 67% for general surgery, 63% for pediatrics, and 61% for internal medicine. When the Program was completed only 3% of obstetrics and gynecology positions were vacant, compared with 21% for internal medicine and 30% for family practice.

Of the 1044 postgraduate year 1 positions for obstetrics and gynecology residencies starting in 1990 entered through the Program, 925 were filled with U.S. medical school seniors, 51 with U.S. medical school graduates who did not go immediately into obstetrics and gynecology, 4 with Fifth Pathway students, 8 with U.S. foreign medical school graduates, 25 with alien foreign medical graduates, 30 with doctors of osteopathy, and 1 with a Canadian medical school graduate. In addition, approximately 100 positions were filled outside the match, 60 from armed forces programs. In 1990 there were approximately 170 senior American medical students who wanted obstetrics and gynecology as their specialty but were not matched with a position; in 1989 there were 80 and in 1988 52.

There are more American medical school graduates interested in careers in obstetrics and gynecology than there are positions, and there is concern that there will be increasing shortages of obstetrician-gynecologists in several regions of the country[1]; therefore, it is important to assess whether the medical students who obtain residency positions in our discipline actually complete the residency or whether there is an excessive attrition rate.

The Council on Resident Education in Obstetrics and Gynecology therefore decided to determine the attrition rate and cause in our residency programs.

Material and methods

At the request of the Council on Resident Education in Obstetrics and Gynecology (CREOG), in 1989 one of the authors (R.M.) sent a survey to each of the 295 obstetrics and gynecology residency program directors in the United States and Canada asking how many residents were currently in their programs, how many had left during the past 2 years, and the reason the residents left. These data were tabulated by the CREOG office.

Results

Of the 295 surveys sent, 265 replies were received (90% response rate) from program directors responsible for 4306 postgraduate year 1 to postgraduate year 4 (or 5) residents per year. On the 265 replies, 117 were from obstetrics and gynecology residency programs within medical schools, 114 from programs affiliated with medical schools, and 34 from institutions with no relationship to a medical school.

During the 2-year period for which data were requested, 299 residents left. Table I indicates the reasons residents left obstetrics and gynecology programs. Eighty-eight residents left to train in another specialty, choosing a variety of fields including pediatrics, internal medicine, family practice, anesthesia, psychiatry, radiation therapy, and surgery. Reasons cited for these changes to other disciplines included stress, demanding work hours, inability to fulfill commitment, unsuitable personality, and disenchantment with the specialty.

Sixty-two residents left to train in other obstetrics and gynecology residencies. Of those residents, 35 were originally from university programs, 16 from medical school–affiliated programs, and 11 from programs not affiliated with a medical school.

Fifty-eight residents were dismissed and 40 residents left their programs because of spouse relocation. The 51 residents who left for miscellaneous reasons, cited issues such as finances, personal illness, family illness, and drug use. In five instances residents left their programs because of issues relating to maternity or child care. We do not know whether residents who left because of spouse relocation, miscellaneous reasons, or dismissal ultimately reentered obstetrics and gynecology programs or residency programs in other disciplines or did not reenter residencies at all.

Table II indicates the number of residents leaving each institution. Nine programs each had 4 residents leave the program. Three of these 9 programs each had only 8 residents, 1 had 10 residents, 2 had 16, 1 had 20, 1 had 21, and 1 had 44 residents. Six programs each had 5 residents leaving the program. One of these programs had 8 residents, 1 had 10, 1 had 11, 1 had 12, and the other 2 had 24 residents each. One 13-resident program had 6 leave.

Comment

There is a growing concern that there will continue to be an increasing shortage of obstetricians and gynecologists to meet the health care needs of American women.[1] Therefore it is important that medical students are carefully counseled in career decisions by informed members of their medical schools. In addition to the internal resources of individual departments and medical schools, more formal programs for career specialty decisions may be available. One such program known to us is the Glaxo pathway evaluation program, which helps students to identify their personal and career goals. In addition to the guidance given to students by their medical schools, the residency selection process should make certain that those individuals selected will have the motivation and capability to complete the residency program and meet the health care, education, and research needs of our discipline.

Ninety percent of programs surveyed by the Council responded, reporting that 299 residents left their programs in a 2-year period (3.47% per year). Only 88 residents left programs specifically because they wished to train in another specialty (1% per year). This suggests that medical school departments of obstetrics and gynecology are providing appropriate counseling and exposure so that the medical students have a reasonable appreciation of the discipline and what the demands and rewards of a residency in this field entail. Sixty-two residents (0.72% per year) left to train in other obstetrics and gynecology residencies. In many instances there were several residents leaving the same program but continuing training in the field. Our survey was not detailed enough to enable us to evaluate why this occurred, but it is likely that in some instances there may have been sudden disruptions in a program. In 40 instances (0.46% per year) residents left programs because of spouse relocation. This is a surprisingly small percentage given the numbers of residents who have spouses with careers and the forced mobility this sometimes entails. Also of note is that only five instances

were reported in a 2-year period in which residents left because of issues relating to maternity or child care. Because approximately 47% of obstetrics and gynecology residents are women and almost 50% of married female residents become pregnant during their residency,[2] this is a very small number.

Fifty-eight residents (0.67%) were dismissed. Program directors and residency selection committees are continually refining their selection processes in an attempt to select the most promising residents. In spite of strict selection criteria it is often difficult to identify the types of problems that ultimately lead to resident dismissal.

In conclusion we feel that 3.47% per year attrition from our programs is not excessive, particularly because many of these residents are not leaving the discipline of obstetrics and gynecology, but rather are changing from one program to another. However, we should continue to reevaluate and refine student career counseling and resident selection processes to keep resident attrition from our discipline and residency programs at a low rate.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Repeated fetal losses associated with antiphospholipid antibodies: A collaborative randomized trial comparing prednisone with low-dose heparin treatment

F. Susan Cowchock, MD,[a] E. Albert Reece, MD,[c] Donald Balaban, MD,[b] D. Ware Branch, MD,[d] and L. Plouffe, MD[e]

Philadelphia, Pennsylvania, New Haven, Connecticut, Salt Lake City, Utah, and Augusta, Georgia

OBJECTIVE: We attempted to compare the use of low-dose heparin with a standard dose of 40 mg prednisone daily (both plus low-dose aspirin) for treatment of pregnant women with antiphospholipid antibody–associated recurrent fetal loss with respect to maternal and perinatal morbidity and efficacy in prevention of fetal death.

STUDY DESIGN: A multicenter randomized trial included 20 patients. Generalizability of results from randomized patients was evaluated by means of additional data from 13 women refusing and 12 women ineligible for randomization. Data from study groups were compared with Fisher's exact test, and generalizability was evaluated with a χ^2 test for trend.

RESULTS: Live birth rates were the same (75%) with either treatment, but "serious" maternal morbidity and the frequency of preterm delivery were significantly higher among women randomly assigned to prednisone ($p = 0.02$ vs $p = 0.006$). Preterm delivery among prednisone-treated women was usually associated with premature rupture of the membranes or preeclampsia. These results could be generalized to the other groups of women ascertained during the course of the study.

CONCLUSIONS: Low-dose heparin should be preferred to prednisone when treatment is indicated for high-risk pregnant women with antiphospholipid antibodies. (Am J Obstet Gynecol 1992;166:1318-23.)

Key words: Heparin, prednisone, antiphospholipic antibodies

The term antiphospholipid antibodies refers to a broad group of autoantibodies including both lupus anticoagulants and antibodies to cardiolipin. Antiphospholipid antibodies have been associated with a history of fetal loss and thrombosis in women with or without systemic lupus erythematosus.[1-7] The predictive value of antiphospholipid antibody tests for fetal death or thrombosis in varied groups of women, with or without a history of fetal loss or treatment, ranges from 48% to 76%.[3, 4, 7] When antiphospholipid antibodies are present, continuing pregnancies may be complicated by thrombosis, preeclampsia, fetal distress, preterm delivery, or low birth weight.[3, 7-9] Successful treatment of such pregnancies with 40 to 60 mg prednisone and 80 mg aspirin daily was first reported by Lubbe et al.[10] in 1983. Rates of live births with treatment, usually aspirin and prednisone, have averaged 60% to 76%.[5, 6]

The morbidity associated with prednisone treatment led to consideration of anticoagulation with heparin to prevent both thrombosis and fetal death in affected pregnancies. The rationale for the use of heparin was the observation of infarction in placentas of affected pregnancies and reports that lupus anticoagulants may interfere with the activation of protein C by thrombin bound to thrombomodulin.[11] Heparin may compensate for deficient levels of protein C(a), or activated protein C, which inactivates clotting factors Va and VIIIa. Heparin was given in anticoagulant doses without aspirin, or in prophylactic doses with low-dose aspirin, in both individual case reports and in the first published series of cases.[12, 13] Rates of live births in the latter were equal to those reported for prednisone-treated women, but both series included some women with only one previous fetal death. Only women with histories of at least two prior fetal losses associated with a confirmed diagnosis of antiphospholipid antibodies were included in this prospective study. We compared pregnancy outcomes after treatment with aspirin plus either prednisone or prophylactic doses of heparin in the first collaborative trial of therapies for affected women.

Material and methods

Eligibility criteria and randomization. All subjects had two or more prior unexplained fetal losses. The diagnosis of an antiphospholipid antibody required two or more positive tests (lupus anticoagulant or anticardiolipin antibodies) over at least a 6-week period. Other accepted causes for recurrent miscarriage or fetal death were excluded. Randomization was performed centrally with a computer-generated sequence of random numbers after pregnancy was confirmed. Written consent, approved by institutional review boards at each investigating center, was obtained from every participant. Women were excluded from randomized treatment assignment when a relative contraindication or indication for the use of one of the treatment drugs was documented. Twelve women were ineligible because of a history of diabetes ($n = 2$), a history of thrombosis outside of pregnancy ($n = 2$), current treatment with prednisone for another indication ($n = 3$), previous fetal loss with one of the treatments (three of four were previously treated with prednisone), or thrombocytopenia ($n = 1$). An additional 13 women refused randomized treatment assignment. Data from patients not randomly assigned to a treatment were collected during the course of the study to investigate possible selection bias and generalizability of results from randomly treated women.

Treatment protocols. Aspirin (80 mg daily) was prescribed for all patients and given throughout pregnancy. Prednisone was given as soon as pregnancy was confirmed, in divided doses of 20 mg every 12 hours. Prednisone doses were lowered in two cases to improve control of insulin-dependent diabetes in the third trimester. Heparin was initiated at a dose of 10,000 U self-administered subcutaneously every 12 hours as soon as a potentially viable pregnancy was documented by ultrasonography (6.5 to 8 weeks). Subsequent doses were adjusted downward by 2000 U until a midinterval activated partial thromboplastin time was within the normal range or similar to prolonged baseline values. The mean daily dose was 17,000 U, similar to dosages for pregnant women on the basis of measurement of the activation of factor X.[15] Two women in the heparin treatment group miscarried before ultrasonographic documentation of pregnancy viability and therefore were not treated. Heparin treatment was not begun until ectopic pregnancy could be excluded by ultrasonography. All women given heparin were also given vitamin D (600 to 800 U) and calcium carbonate (4 gm). Similar supplementation was not advised for women receiving prednisone because corticosteroids primarily affect bone collagen matrix.

Data collection and statistical analysis. Patients came from seven participating centers. The study was initiated in March 1988 and continued through September 1990. Enrollment data included obstetric and medical histories, and the results of a complete blood count, creatinine, antinuclear antibody titer, levels of serum complement, and antiphospholipid antibody test results. The American Rheumatism Association criteria were used for the diagnosis of systemic lupus erythematosus.[16]

Enzyme-linked immunosorption assays for immunoglobulin M and immunoglobulin G class anticardiolipin antibodies were performed at collaborating institutions and repeated on at least one aliquot of serum in a central laboratory according to a previously described method.[17] Positive results were confirmed if the value after subtraction of nonspecific binding fell at or above 2 multiples of the median for a normal obstetric population. These cutoff values were equivalent to >30 GPL (IgG phospholipid units) and >11 MPL (IgM phospholipid units) units using commercially available kits (REAADS Medical Products, Inc., and Kallestad Diagnostics Inc.). All patients had anticardiolipin antibody levels equivalent to or higher than the midpositive range of Harris et al.[18] Tests for lupus anticoagulants included activated partial thromboplastin time (45% of cases) or dilute Russell viper venom time performed on a fresh or fresh-frozen plasma sample in a central laboratory.[19] Abnormal coagulation times (2 SD above the mean) were confirmed by 1 : 1 dilution of the sample with fresh-frozen plasma to exclude clotting factor deficiencies.

Outcome data included medical and obstetric complications. Fetal distress was diagnosed on the basis of nonreassuring fetal heart rate monitoring with or without abnormal ultrasonographic findings (biophysical profile). Deliveries before 37 completed postmenstrual weeks were considered preterm. Low birth weight was defined as birth weight below the 10th percentile for gestational age. We excluded the following complications unrelated to antiphospholipid antibodies or treatment from analysis: two fetal losses (one in patient with incompetent cervix given heparin and one with fetal aneuploidy given prednisone) and two elective preterm deliveries in the heparin group (single cases of discordant twins and placenta previa).

Maternal morbidity was tabulated for those who completed at least 6 weeks of treatment. Morbidity was classified as minor (problems such as thrush or transient nose bleeds), manageable (problems requiring treatment such as gestational diabetes), or serious (potentially life-threatening or with permanent sequelae such as maternal preeclampsia with both hypertension and proteinuria and one case of posterior capsular cataracts).

Statistical analyses. Differences in rates and means between groups were compared with Fisher's exact test (two-tailed) and a standard t test. Generalizability of

Live births in prospectively treated pregnancy	9/12 (75%)	6/8 (75%)
Live births excluding those with just two abortions before 12 wk	6/9 (67%)	4/6 (67%)
Fetal deaths after 12 wk	1/12 (8%)	2/8 (25%)

*Only one woman in whom antiphospholipid antibodies were restricted to IgM class anticardiolipin antibody binding was among those with a history of just two miscarriages before 12 weeks.

results from study patients to the other groups of women was tested with a χ^2 test for trend. The likelihood of a false-negative error and power analysis for sample sizes were calculated with published tables and nomograms.[20,21]

Previous studies suggested that the rate of live births would be approximately 50% for heparin-treated women if treatment were ineffective. The study was continued until statistically significant differences in maternal or fetal morbidity or mortality with either treatment were evident on yearly interim data analysis.

Results

Interim analysis of pregnancy outcomes for 20 women who were eligible for and accepted random assignment to one of the treatments by the end of the second study year is reported here. Equal numbers of women were not assigned to each treatment at this point because allocation was to be balanced when the total reached 50. Obstetric histories, pertinent laboratory studies, and pregnancy outcomes after treatment are summarized in Table I. Women randomly assigned to a treatment had two to four (mean of three) sequential previous abortions. Most (15/20) had at least one fetal death after 12 weeks or had had three or more spontaneous abortions in the first trimester. None had historic or laboratory findings satisfying three or more of the American Rheumatism Association criteria for the diagnosis of systemic lupus erythematosus or an uncomplicated live birth without treatment in the 5 years before the treated pregnancy. Treatment groups were similar with respect to medical and obstetric histories and laboratory results ($p = 0.7$ to 1.0). The frequency of live birth after treatment was 75% in each group. The 95% confidence intervals for these figures were 43% to 95% (heparin group) and 35% to 97% (prednisone group). Live birth rates are also shown after exclusion of women with just two first-trimester miscarriages. This number of randomly assigned patients did not have the power (alpha = 0.05, beta = 0.80) to exclude a 50% difference with respect to rates of live births.

In contrast to the similar live birth rates in the two treatment groups, women randomly assigned to prednisone were significantly more likely to be delivered preterm (6/6 vs 2/8, $p = 0.006$). Preterm delivery was associated with premature rupture of the membranes (3/6 vs 0.9, $p = 0.04$) or preeclampsia (Table II). Preterm delivery was an important problem for infants of prednisone-treated women; on average they were delivered 5 weeks earlier than those in the heparin group (mean of 32 vs 37 postmenstrual weeks, $p = 0.05$).

Maternal morbidity is also shown in Table II for all women treated for at least 6 weeks, including three whose pregnancies ended in fetal death. In contrast to those treated with heparin, women given prednisone were significantly more likely to have a serious complication (preeclampsia and one case of posterior capsular cataracts) ($p = 0.02$) and often had more than one complication.

Selection bias among randomized women was evaluated by comparing study women with women ascertained during the course of the study who refused or were not eligible for randomization (Table III). The eligibility criteria tended to exclude women with systemic lupus erythematosus or "lupus-like" disorders. Thus women not eligible for randomized assignment because of thrombocytopenia or concurrent treatment with prednisone were more likely to have at least three criteria for the diagnosis of systemic lupus erythematosus ($p = 0.01$, compared with randomized women). All women with a history of a fetal death with treatment (usually prednisone) were also assigned to this group. For these reasons ineligible women were probably at higher prior risk for fetal death than the study group. Eligible women refusing randomization were more likely to have an uncomplicated live birth within the

preceding 5 years (p = 0.05). Therefore they may have been at lower prior risk for fetal death than the study group. In spite of these potentially important differences in medical and obstetric histories, women who refused and ineligible women had rates of live births (69% and 67% respectively) similar to those of the randomized group. The overall rate of live births for women with only two first-trimester miscarriages treated with either heparin or prednisone was 92% (11/12, 95% confidence interval 62% to 100%). However, this improvement was not statistically significant compared with the overall rate for those with more (11/12 vs 21/33, p = 0.13).

The generalizability of our observations was evaluated by comparing outcome data from all groups with those from randomized women with respect to treatment (Table IV). There was no trend (p = 0.8) to a difference in rates of live births when prednisone-treated women were compared with those treated with heparin across all groups. The rate of live births for all groups of prednisone-treated women was 68% (13/19, 95% confidence interval 43% to 87%). The rate of live births for all groups of heparin-treated women was 73% (19/26, 95% confidence interval 52% to 88%). This generalized comparison of live-birth rates had the power (alpha = 0.05, beta = 0.80) to exclude a difference of ≥35% between all women given one of these treatments with respect to live births. Live-birth rates with either treatment were therefore 70% ± 25%. However, fetal deaths after 12 postmenstrual weeks tended to occur more frequently among prednisone-treated women (p = 0.15). The increased risk for preterm delivery, in association with premature rupture of the membranes and preeclampsia, observed among women randomly assigned to treatment with prednisone could be generalized with a high degree of confidence to prednisone-treated groups of women who may have been at different prior risk for fetal death.

Comment

We compared pregnancy outcomes for groups of women with antiphospholipid antibodies and repeated pregnancy losses treated with 80 mg aspirin daily and either standard therapy (40 mg prednisone daily) or adjusted low-dose heparin. Interim analysis of the data did not demonstrate a statistically significant difference between these treatments with respect to the likelihood of a live birth or fetal death. The similarity between prednisone- and heparin-treated women in this respect could be generalized to all such women prospectively ascertained and treated by one of the investigators during this study. Using data from all treated women, we could exclude a 35% difference in live-birth rates between women treated with heparin and those receiving prednisone. For both heparin- and prednisone-treated women the live-birth rate was therefore 70% ± 25%.

However, significantly higher rates of preterm delivery, associated with premature rupture of the membranes and serious maternal morbidity (usually preeclampsia), were observed for randomized women treated with prednisone. These could also be generalized to the other groups of women. Premature rupture of the membranes in prednisone-treated patients may be due to glucocorticoid effects on collagen or may reflect an increased prevalence of subclinical amnionitis. Lubbe and Liggins[22] also noted that premature rupture of the membranes occurred in all pregnancies

Frequency of preterm delivery and premature rupture of membranes was calculated for live births; frequency of maternal morbidity was calculated for all women with pregnancies continuing after 12 postmenstrual weeks. *p* Value (two tailed) from χ^2 test for trend across groups for prednisone compared with heparin treatment.

*Two pregnancies that were electively delivered preterm because of placenta previa and discordant twins were excluded from calculations.

†One woman with premature rupture of membranes at 36 weeks was delivered at term.

of corticosteroid-treated women, unless they were delivered preterm for another indication. Preterm delivery in a study of renal transplant patients (generally treated with doses of prednisone in the range of 0.2 mg/kg/day) was partially attributed to abnormal renal function, but the incidence of premature rupture of the membranes was also higher than expected.[29] In contrast to these observations, no serious morbidity was observed among groups of heparin-treated women. The absence of heparin-associated thrombocytopenia or osteoporotic fractures in heparin-treated women could be due simply to the low frequency of these complications or it could reflect the use of low doses together with prophylactic low-dose aspirin (thrombocytopenia) and supplemental calcium and vitamin D (osteopenia).

From our interim data analysis further pursuit of a possible significant difference in live-birth rates would require that at least 100 women be randomly assigned to either heparin or prednisone treatment, because any difference in this respect between groups was probably ≤25%. Continued evaluation of groups of randomly

treated women with live-birth rates in the range of 70% for a difference of this size did not appear to be justified because of the statistically significant and clinically important risks associated in this study with prednisone treatment. Analysis of the data collected suggested to us that low-dose heparin would be the best choice when treatment is indicated for high-risk pregnant women with antiphospholipid antibodies. Lockshin et al.[25] also concluded that prednisone (usually given in lower doses) did not improve live-birth rates in their series of cases. We did not compare these treatments with aspirin or placebo because the group of women studied were those considered to be at high risk for both fetal loss and puerperal thrombosis. Furthermore, it would be difficult to blind randomly assigned women to the physical effects associated with corticosteroid treatment. Future trials might compare the efficacy of heparin or aspirin with placebo or usual care of women whose medical or obstetric history suggests that they are at low risk for these serious complications. Those at low risk may include women with just two miscarriages before 12 weeks and no history of thrombosis. The live-birth rate for 12 such women treated with either heparin or prednisone was 92% (95% confidence limits 62% to 100%). Other pregnancy outcome parameters such as the frequency of preeclampsia, preterm delivery, and birth weight could be used as surrogate measures of treatment efficacy.

We appreciate the editorial advice of J. Bruce Smith, MD, Jefferson Medical College.

Necrotizing fasciitis of the vulva

Hale Stephenson, MD, Deborah J. Dotters, MD, Vern Katz, MD, and William Droegemueller, MD
Chapel Hill, North Carolina

OBJECTIVE: We attempted to characterize the natural history of necrotizing fasciitis of the vulva.
STUDY DESIGN: The records of 29 nonpregnant women with necrotizing fasciitis of the vulva were evaluated.
RESULTS: These women experienced a rapidly progressing polymicrobial infection. Initially, the infections in many women were thought to be labial cellulitis, appearing mild and innocuous. Delays in recognition and aggressive surgical management were associated with increased morbidity and mortality. Of 15 women with a delay >48 hours between presentation and treatment, 11 died. Twenty of 29 (69%) were diabetic, accounting for 11 of the 14 deaths.
CONCLUSION: Early diagnosis and aggressive surgical debridement in spite of mild symptoms will improve outcome in this serious disease process. (Am J Obstet Gynecol 1992;166:1324-7.)

Key words: Necrotizing fasciitis, diabetes, surgical debridement

Necrotizing fasciitis of the vulva is a surgical emergency.[1-10] This disease may present as an innocuous-appearing labial pustule, and this superficial appearance may mask the underlying pathologic condition. The infection is polymicrobial and treatment is wide excision of infected tissue.[1-10] Since the first descriptions of the disease 100 years ago, authors have called attention to the need for aggressive surgical therapy.[1-10] This report describes our clinical experience over an 8-year period.

Material and methods

We reviewed the medical records of female patients with cellulitis, necrotizing fasciitis, and soft tissue infections of the vulva or the lower abdomen. Twenty-nine patients were examined at North Carolina Memorial Hospital and at Wake Medical Center, during the period January 1983 to January 1990. Included in this study were patients with evidence of primary infection and necrosis of the soft tissue of the external genitalia. Patients with postoperative wound infections, puerperal infections, or perirectal infections were excluded. Patients with inflammatory bowel disease, malignancy, or previous radiation also were excluded. These exclusions were made to focus on necrotizing fasciitis of vulvar origin, unrelated to other genital disease processes.

Results

The median age of the 29 patients was 59 years, with a range from 28 to 74 years. Fifteen patients had evidence of hypertension or peripheral vascular disease, 8 had chronic renal insufficiency, and 20 were morbidly obese (>50% above ideal body weight). Twenty-four patients were black and 5 were white. Hospital stay ranged from <24 hours to 166 days. Fourteen of 29 patients (48%) died. Table I summarizes the characteristics and clinical course of these patients. Initial presentations varied considerably from chief complaints of mild perineal pain to coma. Seventeen of 29 presented with temperatures >38° C. Two had hyperthermia with temperatures of 36.8° and 35.6° C, respectively. White blood cell counts were >13,000/mm³ in 18 patients.

Twenty patients were diabetic, and 19 of these had abnormal glucose levels on admission. Sixteen presented with blood glucose levels >250 mg/dl. One woman was referred with an intravenous insulin infusion. One patient presented in diabetic ketoacidosis with a blood glucose level of 1426 mg/dl. Another diabetic patient was hypoglycemic on admission with a blood glucose level of 40 mg/dl.

The time course between the patient's presentation to the health care system and definitive surgical therapy varied widely. In general, the longer the delay in surgical debridement, the greater the morbidity and mortality. We did not quantify this relationship because the treatments at other institutions varied widely, as did time from onset of symptoms to admission. Twelve of the 14 deaths occurred in patients with >48 hours between presentation and definitive surgical therapy at our institution. Of the six patients operated on within 12 hours of presentation, 5 survived. The other patient

*Completed days from hospital admission (at any hospital) until surgical debridement at our institution.

was in septic shock at initial presentation and she eventually died. Seven patients underwent wide debridement between 12 and 14 hours after presentation to a physician. One of these patients was in septic shock at initial presentation, and she died after transfer to our institution. The other 6 survived. Of 8 women operated on between 24 and 48 hours after initial presentation, 2 survived. Finally, only 2 of the 8 subjects who did not undergo operations until ≥48 hours after presentation survived. Length of hospital stay and complications followed similar trends. Three patients had cardiopulmonary arrests; 2 survived, one with severe neurologic deficit. All 3 of these patients had >48 hours between admission and definitive surgical treatment. Adult respiratory distress syndrome developed in 2 patients. Both were in the group with a 48-hour delay in surgical treatment.

Twenty-eight patients were eventually managed with wide local excision and debridement of affected tissues. Nine patients required a second surgical debridement, and 5 other women required three or more operative procedures. Ten patients had skin grafting procedures performed before discharge. Nineteen patients were admitted to the intensive care unit postoperatively. Sixteen of 29 patients required transfusions, with 11 patients required ≥4 U of packed red blood cells.

All patients received broad-spectrum antibiotic therapy including a penicillin or cephalosporin, an aminoglycoside, and clindamycin or metronidazole. Wound cultures yielded more than one organism in 23 patients (79%). Sixteen women (55%) had three or more organisms cultured (Table II). The most commonly cultured organisms were *Peptostreptococcus* (14 patients), *Bacteroides fragilis* (12 patients), and *Escherichia coli, Enterococcus,* and β-hemolytic streptococci. In one patient culture grew *Clostridium tetani* in addition to *E. coli* and *B. fragilis*. She was included in the analysis because *C. tetani*, unlike *Clostridium perfringens*, does not produce its abnormality through myonecrosis.

Comment

Necrotizing fasciitis was described by Joseph Jones, a Confederate Army surgeon, in 1871 as a clinical process wherein, "I have seen the skin in the affected spot

melt away . . . in ever increasing circles."[11] The modern definition of necrotizing fasciitis is a severe infection of the soft tissue in which the major distinguishing characteristic is the presence of extensive necrosis and undermining of the skin, with involvement of tissues up to and occasionally including the deep fascia.[1-10] Our experience suggests that severe pelvic cellulitis and necrotizing fasciitis represent a continuum of clinical conditions requiring aggressive surgical therapy. A definitive diagnosis of necrotizing fasciitis is dependent on the histologic verification of leukocytic infiltration of the fascia, with thrombosis and focal necrosis.[10, 12] However, the management of this disease does not depend on obtaining histologic diagnosis, and the accuracy of frozen section is unknown.

Necrotizing fasciitis of the vulva and perineum is particularly prevalent among diabetics.[2, 5, 6, 8, 12] Among diabetic women, necrotizing fasciitis is particularly prevalent in the vulva and perineum.[6] Rea and Wyrick[8] presented 44 cases of necrotizing fasciitis, among which 8 patients were diabetic. Five of these 8 died (63%). Roberts and Hester[5] reported six cases of necrotizing infections among diabetic patients, including three deaths (50%). Roberts[6] later described 16 cases of necrotizing fasciitis, including 15 among women with diabetes. There were five deaths. Our series includes 11 deaths among 20 diabetic women. It is believed that the extreme mortality among diabetics with necrotizing fasciitis is attributed to the combination of diminished cell-mediated immunity and poor tissue perfusion as a result of peripheral vascular disease.[2] Peripheral vascular disease also has been noted to be a risk factor for this disease. Ten patients had evidence of vascular disease in this series.[3, 8, 10]

Our series was selected to emphasize the patient who represents with vulvar disease not specifically related to other pathologic conditions. This is not to underemphasize that necrotizing fasciitis may occur in many settings. Pregnant patients may also be affected by this disease, with mortality rates of up to 50%.[13-15]

Survival among patients with necrotizing fasciitis requires both early recognition and an appreciation for the associated morbidity and mortality. Patients found to be in high-risk groups need immediate hospitalization and aggressive surgical and antimicrobial therapy.[1, 7, 10, 12] In the current series the 8 patients who had a delay of ≥48 hours in obtaining surgical treatment had a mortality of 75%. Of the 5 patients whose condition was initially managed with simple incision and drainage, all eventually needed wide debridement and one patient died. The delays in surgical treatment occurred at local emergency rooms, gynecologist's offices, and general medicine services at university hospitals. We believe delays are due to the failure of physicians to recognize the severity of this disease process. With a simple incision and drainage procedure, clinicians may not appreciate the underlying inflammation and necrosis. Adequate anesthesia is an absolute necessity for the clinician to obtain debridement that is sufficiently wide.

The earliest signs of the infection are local induration, edema, and marked tenderness.[2, 7, 10, 12] On occasion, a purulent discharge is noted from the affected tissues. It is paramount that clinicians appreciate that the degree of tissue necrosis cannot be predicted by the cutaneous signs. Two patients in our series presented with pustules with "slight" induration, and the condition was managed with hot compresses. Both patients eventually died. It is important that the absence of visible purulent material does not exclude the diagnosis of necrotizing fasciitis. In the course of necrotizing fasciitis, the superficial skin changes may be minimal, even though deeper tissue necrosis is under way. Late signs include skin discoloration and local analgesia, which appear after the infection has spread.[2, 7, 10, 12] At this point the blood supply and innervation of the overlying tissues are interrupted because of thrombosis of vessels and resultant ischemia. Serum calcium levels may be low because of binding with necrosed fat. Crepitus also appears as a late sign because gas-forming anaerobes predominate in the ischemic tissues.[2, 4, 6-9]

Necrotizing fasciitis is a polymicrobial infection. Both aerobic and anaerobic organisms are involved.[2, 4, 6-9, 14] In this series 23 patients were found to have more than one organism and 16 had three or more organisms. This polymicrobial nature of the infection underscores the synergistic activity of the bacteria. Antimicrobial therapy should thus reflect the wide spectrum of bacterial involvement. Antibiotics are an important component in the therapy of necrotizing infections. However, without debridement, antibiotics alone are insufficient therapy. In our series two of three patients whose

condition was initially managed solely with antibiotics died, with no patients' infections resolving with antibiotics alone. Crosthwait[16] reported progression of the infection in 10 of 19 patients treated with antibiotics alone.

The optimal management is wide debridement of all affected tissues. Authors have advocated both blunt undermining of the soft tissue along the fascial plane, until the resistance of viable tissue is encountered,[1, 8-10] and sharp dissection with excision of the full thickness of affected tissue, until bleeding is encountered.[2, 8, 10] Neither method has been shown to be superior, and both techniques were used in our series. The important commonality of both these techniques is that all necrotic tissue is removed.[2, 10] The patient and her family should be prepared for extensive debridement and potentially prolonged hospitalization.

The morbidity and mortality of this disease can be prevented only by a high degree of clinical suspicion. As this series has demonstrated, minimizing the treatment of necrotizing fasciitis does not help the patient.

The California Maternal Serum α-Fetoprotein Screening Program: The role of ultrasonography in the detection of spina bifida

Lawrence D. Platt, MD,[a] Lisa Feuchtbaum, MPH,[b] Roy Filly, MD,[c] Linda Lustig, MS,[b] Michele Simon, MPH,[b] and George C. Cunningham, MD, MPH[b]

Los Angeles and San Francisco, California

Between January 1988 and June 1990, 161 cases of open spina bifida were identified by the California Maternal Serum α-Fetoprotein Screening Program. Eight percent of these cases were not diagnosed by an initial ultrasonographic evaluation. Three defects were not recognized until birth. Ultrasonography is inadequate to identify all cases of open spina bifida. (Am J Obstet Gynecol 1992;166:1328-9.)

Key words: Neural tube defects, α-fetoprotein, ultrasonography

A number of recent articles[1] and letters[2, 3] have suggested an ongoing controversy over the necessity of amniocentesis in the prenatal diagnosis of neural tube defects. Wald et al.[2] summarized the existing studies of spina bifida occurring in women at high risk of having a fetus with a neural tube defect. Thirty-one of 261 (12%) were not detected by ultrasonography. Responding to this report, Nadel et al.[3] contended that only three studies cited by Wald et al. were published after 1986, the year that the ultrasonographic intracranial signs for spina bifida were first reported. In April 1986 offering maternal serum α-fetoprotein (AFP) screening became mandatory in the State of California. This experience with large numbers of pregnant women has allowed new observations of the role of ultrasonography in the detection of neural tube defect. We report our experience with 161 cases of spina bifida ascertained through the California Maternal Serum α-Fetoprotein Screening Program between January 1988 and June 1990.

Material and methods

During the period from January 1988 through June 1990, >640,000 women were screened in the California Maternal Serum α-Fetoprotein Screening Program. Cases with elevated maternal serum AFP values were offered an ultrasonographic examination by an experienced sonographer at one of the 20 prenatal diagnostic centers throughout the State of California. Each center designated as an AFP prenatal diagnosis follow-up center must have at least one sonographer who meets criteria defined by the Genetic Disease Branch. These criteria include board certification, fellowship training in maternal-fetal medicine, or ultrasonography with an emphasis on high-risk obstetric ultrasonographic examinations. In addition, personal experience must include 500 detailed second-trimester examinations specific for the identification of birth defects and a yearly minimum case load. When appropriate, amniocentesis was offered to these patients and AFP testing of the amniotic fluid was performed. If the amniotic fluid AFP level was elevated, an acetylcholinesterase level was ascertained.

Approximately 92% of patients with abnormal maternal serum AFP values had follow-up through one of the program's diagnostic centers. We report our results only from those cases.

Results

Out of the 161 cases of open spina bifida identified, 148 (91.9%) could be said to be detected by ultrasonographic examination. These 148 cases include those diagnosed either with a suspicious finding on the sonogram alone or by ultrasonography before amniocentesis. The remaining 13 cases (8.1%) were not identified by initial ultrasonographic examination. Ten cases were eventually recognized with ultrasonography but only after an amniocentesis yielded an elevated amniotic fluid AFP level and a positive acetylcholinesterase test result. The other three cases were not diagnosed until birth. In two of these instances ultrasonography failed to detect any anomalies and the patients declined amniocentesis. In the third case ultrasonographic measurements of the fetus resulted in a redating of the

6/1/35995

pregnancy. Recalculation of the maternal serum AFP on the basis of this finding placed the value in the negative range and amniocentesis was not performed. Two additional cases of closed spina bifida (not included in the 161 cases) were also missed on ultrasonographic examination. These patients had maternal serum AFP values of 0.57 and 0.62 multiple of the median and were referred for follow-up because of a low maternal serum AFP value. The amniotic fluid AFP values for both were within the normal range, and ultrasonography failed to detect any anomaly.

Comment

The 13 cases of open spina bifida missed on initial ultrasonographic examination occurred in nine of the prenatal diagnostic centers, with one center reporting three of the cases. The data presented in this report are post 1986, the year intracranial signs were first reported. Further, the California AFP program has specific criteria for prenatal diagnostic centers performing AFP follow-up. These include the use of sonographers with extensive training in prenatal diagnosis and second-trimester examinations. However, even in these centers, it is possible that some sonographers have less experience than one of their colleagues and thus are even more likely to miss a defect.

The ultrasonographic detection rate of 91.9% for open spina bifida is significantly enough below 100% to warrant the offering of amniocentesis for patients with elevated maternal serum AFP results. In regard to decision making at moderate maternal serum AFP elevations, four of our 13 missed cases of open spina bifida had multiple of the median values below 3.0. On the basis of our data, we caution against the recommendation to forego amniocentesis with elevated maternal serum AFP results. We agree with Nadel et al.[3] that patients deserve to make an informed decision about whether to proceed with amniocentesis, as long as these choices are based on all available information. It seems reasonable that reassigning risks of neural tube defects on the basis of maternal serum AFP values, the subsequent ultrasonographic findings, and the individual's personal experience before amniocentesis may be indicated in the future.

In an attempt to explain why so many experienced centers missed overt lesions on ultrasonography, a number of factors, including obesity and previous abdominal surgery, may interfere with adequate diagnosis. Transvaginal imaging may decrease image degradation caused by obesity in some patients with high maternal serum AFP values and thus enhance diagnosis, particularly if the head of the fetus is near the cervix. However, transvaginal imaging has a limited field of view and limited maneuverability, both of which decrease its applicability.

The knowledge that amniocentesis will be offered to women whose scans do not reveal an obvious abnormality may influence the detail of those scans. However, not all patients elect to have an amniocentesis, and thus some cases go undetected.

In summary, our experience with the detection of neural tube defects suggests that ultrasonography remains inadequate as a single entity to identify all cases of open spina bifida.

We acknowledge the following California Maternal Serum α-Fetoprotein Screening Program prenatal diagnosis centers that contributed cases during the study period: California Prenatal Diagnostics Institute; Cedars-Sinai Medical Center; Children's Hospital of Los Angeles; Children's Hospital of Northern California; The Genetics Institute; Harbor–University of California, Los Angeles Medical Center; Kaiser-North, Kaiser Permanente Medical Care Program; Kaiser-South, Kaiser Permanente Medical Group; Los Angeles County–University of Southern California Medical Center; Loma Linda University Medical Center; Long Beach Memorial Medical Center; Prenatal Diagnostics, Inc.; Stanford University School of Medicine; University of California, Davis Medical Center; University of California, Irvine; University of California, Los Angeles; University of California, San Diego; University of California, San Francisco; Valley Children's Hospital.

Fetal humeral length to detect Down syndrome

Siegfried Rotmensch, MD, Jia-Sen Luo, MD, Marco Liberati, MD, Kathleen Belanger, PhD, Maurice J. Mahoney, MD, and John C. Hobbins, MD

New Haven, Connecticut

OBJECTIVE: Our aim was to evaluate the utility of ultrasonographic humeral length measurements for detection of fetuses with Down syndrome in the midtrimester of gestation.

STUDY DESIGN: Ultrasonographic biometry data obtained before genetic amniocenteses on 43 fetuses with Down syndrome and 204 randomly chosen normal fetuses were analyzed. Regression equations relating biparietal diameter to humeral length and femoral length were used to calculate ratios of observed-to-expected length and sensitivity and specificity at various cutoff points.

RESULTS: Humeral length in Down syndrome fetuses was significantly shorter than in normal controls ($p < 0.001$). A ratio of 0.90 for observed/expected humeral length yielded a sensitivity of 28%, a specificity of 91%, and positive predictive values of 1.23% and 0.41% in populations at risk for Down syndrome of 1 in 250 and 1 in 750, respectively. The equivalent ratio for femoral length yielded a sensitivity of 19%, a specificity of 91%, and positive predictive values of 0.87% and 0.28% for baseline risks of 1 in 250 and 1 in 750, respectively.

CONCLUSIONS: The sensitivity of fetal humeral length measurements for Down syndrome detection in our hands was remarkably lower than previously reported. Independence of this parameter from currently used serum screening markers has not been established; therefore implementation in screening programs is not advisable at this point. (Am J Obstet Gynecol 1992;166:1330-4.)

Key words: Humeral length, Down syndrome, ultrasonography

The role of ultrasonographic screening for Down syndrome is still evolving. Nuchal fold thickening,[1] hypoplasia of the middle phalanx of the fifth digit,[2] short femoral length,[3, 4] and cardiac defects[5] have been proposed as ultrasonographic markers for trisomy 21 fetuses. A recent study by FitzSimmons et al.[6] suggested that upper-extremity long bones were more frequently shortened than the lower extremities in postmortem specimens of Down syndrome fetuses. These findings were confirmed in an ultrasonographic study of 24 Down syndrome fetuses under highly standardized scanning conditions.[7] The current study evaluates humeral length measurements obtained from 43 Down syndrome fetuses and compares the screening utility of this parameter to femoral length measurements and a combination of the two.

Material and methods

From Jan. 1, 1985 to Dec. 31, 1990, 132 fetuses were prenatally diagnosed with Down syndrome at the Division of Maternal-Fetal Medicine and the Department of Human Genetics, Yale University. We analyzed ultrasonographic biometry data of 43 Down syndrome fetuses, with a gestational age between 15 and 21 menstrual weeks, who were scanned before amniocentesis for advanced maternal age. Only scans with complete data on the biparietal diameter (BPD), humeral length, and femoral length were included in the study. All scans in which the fetal karyotype was known at the time of the examination were excluded from the study. The ultrasonographic examinations were performed by more than 15 sonographers with varying levels of experience and training.

Ultrasonography equipment used during the study period included General Electric models RT 2600 and 3000, Ultramark 4 and Ultramark 9 (Advanced Technology Laboratories), Acuson model 128, and Aloka models 650 and 680 (Corometrics). Measurements were obtained with linear, sector, and curvilinear transducers, based on sonographer preference. The BPD was obtained in the axial plane, at the level of the thalami, third ventricle, and cavum septum pellucidum. The calipers were placed on the outer and inner borders of the proximal and distal skull plates, respectively. Humeral and femoral length measurements were performed in the longest dimension of the bone.

Our control group consisted of 204 fetuses with normal karyotypes who were scanned at the same gestational age interval during this 6-year period. To control for variations in scanning technique, equipment, and cumulative experience during the study period, each

Down syndrome fetus was matched with five karyotypically normal fetuses scanned in the same year. Systematic sampling was performed by dividing the total number of genetic amniocenteses for advanced maternal age during each 1-year period by a factor that would provide five control cases per affected case. When data from a selected record were incomplete, the record was deleted without replacement. This resulted in a control group of 204 cases.

Regression analysis was performed to evaluate the relationships between BPD and humeral length, as well as between BPD and femoral length. An expected humeral and femoral length was then calculated from the regression equation for each BPD. A ratio of observed-to-expected humeral length and femoral length was used to determine the specificity, sensitivity, and positive predictive value of the 43 Down syndrome fetuses.

Selective data from this data set will also be evaluated in the future as part of a multicenter study initiated by Dr. Charles Lockwood.

Results

Table I lists individual BPD, femoral length, and humeral length measurements in 43 Down syndrome fetuses. The regression equation relating BPD to humeral length in this population is: Expected humeral length $= -5.4282 + (0.7542 \times \text{BPD})$; $R^2 = 0.77$; $p < 0.001$. Fig. 1 shows a graphic display of the regression line (line a) of humeral length on BPD ± 2 SD, obtained from 204 karyotypically normal fetuses. Line b represents the regression line for the 43 Down syndrome fetuses. Lines a and b are statistically different ($p < 0.001$).

Fig. 2 shows individual values for humeral length in relation to BPD for 43 Down syndrome fetuses plotted on the regression line from the control fetuses with 95th and 5th percentile limits. In spite of the statistically significant difference between regression equations for normal and Down syndrome fetuses (Fig. 1), only one out of 43 measurements was below the 5th percentile. Eight fetuses had humeral length measurements above the expected value and two fetuses had measurements at or above the 95th percentile.

The regression equation for femoral length on BPD in Down syndrome fetuses was: Expected femoral length $= -6.4047 + (0.7849 \times \text{BPD})$; $R^2 = 0.74$; $p < 0.001$.

The regression lines of femoral length on BPD in the normal and Down syndrome groups were statistically different ($p < 0.05$). In 12 cases the humerus was equal in length to the femur; in 22 cases the humerus was shorter and in nine cases longer than the femur.

Table II shows the sensitivity, specificity, and positive predictive value for various measured-to-expected humeral length ratios in women at risk for Down syndrome of 1 in 250 and 1 in 750. A "cutoff" point of 0.90 for measured-to-expected humeral length identifies 12 out of 43 Down syndrome fetuses (28% sensitivity) and has a false-positive rate of 8.8%. The positive predictive value is 1.23% in a population at risk of 1 in 250, which is equivalent to the risk that a fetus of a 35-year-old woman in the mid second trimester would have Down syndrome. In a population at risk for Down syndrome of 1 in 750 (second-trimester risk at age 28), the same cutoff point of 0.90 would yield a positive predictive value of 0.41%.

Respective data on various measured-to-expected femoral length ratios are shown in Table III. Neither sensitivity nor positive predictive value is as good when femoral length is used as compared with humeral length. When humeral and femoral length measurements were combined (ratio ≤0.90 of measured-to-ex-

pected length in either humerus or femur), a 30% sensitivity was obtained. However, positive predictive values for baseline risks of 1 in 250 and 1 in 750 were 1.08% and 0.36%, respectively. When both humeral and femoral lengths were combined, whereby a positive finding occurs only when both limbs are short, the specificity was improved but the positive predictive value was lower than for humeral length alone (Table IV).

Comment

Short stature is a well-recognized feature of Down syndrome. Whether shortening of the long bones in the midtrimester fetus is sufficient to aid in the prenatal diagnosis of Down syndrome is controversial. Lockwood et al.[3] and Benacerraf et al.[8] found that the femoral length is significantly shortened in the midtrimester Down syndrome fetus. Lockwood et al.[3] calculated a 50% to 70% sensitivity with a BPD/femur ratio of 1.5 SD above the normal population mean, and Benacerraf et al.[8] reported a 68% sensitivity with a ratio of 0.90 measured/expected femoral length. However, other authors obtained remarkably lower sensitivities.[9] An evaluation of long-bone length in 37 postmortem specimens of Down syndrome fetuses by FitzSimmons et al.[6] found that most measurements fell below the regression lines for normal controls. Furthermore, their data suggested that upper-extremity bones were more frequently shortened than were lower-extremity bones. Benacerraf et al.[7] reported that ultrasonographic measurements of humeral length in 24 midtrimester Down syndrome fetuses were significantly shorter than those in normal controls. An observed/expected humeral length ratio of 0.90 had a 50% sensitivity, a false-positive rate of 6.25%, and a 3.1% positive predictive value in a population at risk for Down syndrome of 1 in 250. Analysis of femoral length in this population of Down syndrome fetuses showed a lower sensitivity (41.6%).

Our data on 43 Down syndrome fetuses confirm that humeral length is significantly shorter in Down syndrome fetuses than in normal controls. Furthermore,

Table II. Sensitivity, specificity, and positive predictive values for different measured/expected humeral length ratios in women at risk for having a Down syndrome fetus of 1 in 250 and 1 in 750

Measured/expected humeral length	*Sensitivity*	*Specificity*	*Positive predictive value*

0.92	0.92	0.16	0.90	0.67	0.22

a measured-to-expected humeral length ratio of 0.90 identified more Down syndrome fetuses (28%) than did the equivalent ratio for the femur (19%). However, the sensitivity of this ratio in our study was significantly lower than that in the study by Benacerraf et al. This discrepancy could be partially explained by differences between the two ultrasonography laboratories and in study design. Whereas Benacerraf et al. collected cases during a 14-month period, our cases were collected during a 6-year period. It is obvious that ultrasonographic expertise and ultrasonography equipment have changed remarkably in a 6-year period, and less uniformity must be assumed. There were also more sonographers who contributed to this study, as well as a larger variety of ultrasonography equipment and transducers. Differences in long-bone measurements with varying types of ultrasonography transducers have indeed been demonstrated.[10] The higher sensitivity obtained by Benacerraf et al. suggests increased screening efficiency when sonographers and equipment are highly standardized in one laboratory. This also implies that every ultrasonography laboratory should determine its own sensitivity in screening with ultrasonographic measurements. Since our data were collected on a variety of machines, they might be more representative of the inherent variability among various laboratories.

Furthermore, we exclusively evaluated Down syndrome cases for which all three measurements, BPD, humeral length, and femoral length, were available. We assumed that humeral length measurements were not obtained if the measurement was not recorded. It cannot be excluded that humeral length measurements were actually obtained, but discarded, when a sonographer erroneously perceived a disproportionately small humerus to be the result of a measurement error rather than a true growth disturbance.

Since women above the age of 35 are offered amniocentesis for karyotype determination on a routine basis, ultrasonographic humeral length screening would be more applicable to the general population, with an average baseline risk of 1 in 750 for trisomy 21. On the basis of our findings, a positive predictive value of 0.41% could be expected in this population. For every Down syndrome fetus identified in this fashion, 244 amniocenteses would have to be performed on karyotypically normal fetuses. Therefore a measured-to-expected humeral length ratio of 0.90 would

signify a risk for Down syndrome similar to that of maternal age of 35 years, for which routine amniocentesis is currently offered. However, only 5% of the pregnant population are older than 35 when they are delivered.[11] Since 8.8% of our normal controls were below the cutoff ratio of 0.9, implementation of this screening tool would require an additional 8.3% genetic amniocenteses in the general population, with the assumption that fetal humeral length is independent from maternal age. Furthermore, the statistical independence of this screening tool from currently used serum markers for Down syndrome has not been established. Therefore it is conceivable that a substantial portion of fetuses identified by humeral length screening would also be identified by screening with maternal serum α-fetoprotein, human chorionic gonadotropin, and estriol.[12] Such a dependence of parameters would diminish the relative contribution of humeral length screening.

When humeral and femoral length measurements were combined, a cutoff point of 0.90 for observed-to-expected length ratio did not increase the sensitivity obtained for humeral length measurement alone. This finding probably reflects the large degree of concordance in humeral and femoral shortening of Down syndrome fetuses. Small stature in Down syndrome appears to affect all long bones, as suggested by FitzSimmons et al., but is more pronounced in the humerus. Therefore upper- and lower-extremity measurements cannot be used as independent parameters for screening.

Our data support reports by FitzSimmons et al.[6] and Benacerraf et al.[7] of shorter humeral length measurements in midtrimester Down syndrome fetuses, as compared with their normal counterparts. Furthermore, the fetal humerus in Down syndrome appears to be relatively more shortened than the femur. However, the low sensitivity of humeral length screening in our hands and the uncertainty about the statistical independence of this parameter from serum markers for Down syndrome do not support its current use in screening of the general population.

NORPLANT® SYSTEM
levonorgestrel implants

Lasts 5 years...yet is reversible

Serious as well as minor side effects may occur. The most common side effect which has been observed is menstrual bleeding irregularities.

Please see brief summary of prescribing information on the following page.

©1992, Wyeth-Ayerst Laboratories. 70443A

NORPLANT® SYSTEM

levonorgestrel implants

Lasts five years…yet is reversible

BRIEF SUMMARY OF PRESCRIBING INFORMATION. CONSULT THE PACKAGE LITERATURE FOR FULL PRESCRIBING INFORMATION.

Indications and Usage

The NORPLANT SYSTEM is indicated for the prevention of pregnancy and is a long-term (up to 5 years) reversible contraceptive system. The capsules should be removed by the end of the 5th year. New capsules may be inserted at that time if continuing contraceptive protection is desired.

Contraindications

1. Active thrombophlebitis or thromboembolic disorders. 2. Undiagnosed abnormal genital bleeding. 3. Known or suspected pregnancy. 4. Acute liver disease; benign or malignant liver tumors. 5. Known or suspected carcinoma of the breast.

Warnings

A. WARNINGS BASED ON EXPERIENCE WITH THE NORPLANT SYSTEM

1. *Bleeding Irregularities* — Most women can expect some variation in menstrual bleeding patterns. Irregular menstrual bleeding, intermenstrual spotting, prolonged episodes of bleeding and spotting, and amenorrhea may occur, and could mask symptoms of cervical or endometrial cancer. Overall, these irregularities diminish with continued use. Because amenorrhea may occur, missed menstrual periods cannot serve as the only identifier of early pregnancy. Perform pregnancy tests whenever pregnancy is suspected. If pregnancy occurs, the capsules must be removed. Hemoglobin concentrations found in clinical trials generally indicated that reduced menstrual blood loss is associated with NORPLANT SYSTEM use. Blood loss resulting in hemoglobin values consistent with anemia occurred rarely.

2. *Delayed Follicular Atresia* — Atresia of the follicle is sometimes delayed, resulting in enlarged follicles that are clinically indistinguishable from ovarian cysts. In the majority of women, enlarged follicles disappear spontaneously. Rarely, they twist or rupture and surgical intervention may be required.

3. *Ectopic Pregnancies* — Ectopic pregnancies have occurred among NORPLANT SYSTEM users, although clinical studies have shown no increase in the rate of ectopic pregnancies per year among NORPLANT SYSTEM users as compared with users of no method or of IUDs. The incidence among NORPLANT SYSTEM users (1.3 per 1000 woman-years) was significantly below the rate estimated for noncontraceptive users in the U.S. (2.7 to 3.0 per 1000 woman-years). Ectopic pregnancy risk may increase with duration of NORPLANT SYSTEM use and increased weight of the user. Rule out ectopic pregnancy in any patient presenting with lower-abdominal pain.

4. *Breast-feeding* — Steroids are not the contraceptives of first choice for lactating women. Levonorgestrel has been identified in breast milk. Limited data suggests no significant effects on infant growth or health when mothers used the NORPLANT SYSTEM beginning 6 weeks after parturition.

5. *Foreign-body Carcinogenesis* — Rarely, cancers occur at foreign-body intrusion sites or old scars. None has been reported in NORPLANT SYSTEM clinical trials and risk to users is judged to be minimal.

6. *Thromboembolic Disorders* — Remove capsules if active thrombophlebitis or thromboembolic disease develops. With prolonged immobilization removal should be considered.

B. WARNINGS BASED ON EXPERIENCE WITH COMBINATION (PROGESTIN PLUS ESTROGEN) ORAL CONTRACEPTIVES (OCs)

Note: Many of the side effects or risks listed below are thought to be estrogen-related; the association of the NORPLANT SYSTEM progestin-only method to these risks is unknown.

1. *Cigarette Smoking* — Cigarette smoking increases the risk of serious cardiovascular side effects from combined OC use. Risk increases with age and heavy smoking (≥15 cigarettes/day) and is quite marked in women over 35 years old.

2. *Elevated Blood Pressure* — Increase in blood pressure has been reported in combination OC users; prevalence increases with long exposure.

3. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease is associated with combination OC use. Estimate of relative risk is 4- to 11-fold higher for users vs. nonusers.

Cerebrovascular Disorders: Combination OCs increase the relative and attributable risk of cerebrovascular events (thrombotic and hemorrhagic strokes). Generally, risk is greatest among hypertensive women > 35 years of age who smoke.

Myocardial Infarction (MI): An increased risk of MI has been attributed to combined OC use. This is thought to be primarily thrombotic in origin and related to the estrogen component. Increased risk occurs primarily in smokers or women with other underlying risk factors for coronary-artery disease. Relative risk of heart attack for combined OC users is estimated as 2 to 6 times that for nonusers. Absolute risk is very low for women under 30 years old.

Studies indicate a significant trend toward higher MI and stroke rates with increased progestin doses in combination OCs. However, recent data indicated no increased MI risk with past use of levonorgestrel-containing OCs.

4. *Carcinoma* — Recent evidence in the literature suggests no association between OC use and increased risk of breast cancer in the overall population of users. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. Some of these same studies have shown an increased relative risk of breast cancer in certain subgroups; no consistent pattern has been identified. Some studies suggest an association between combination OCs and an increase in the risk of cervical intra-epithelial neoplasia in some populations of women. The extent to which such findings may be due to differences in sexual behavior and other factors remains controversial. A cause-and-effect relationship between combined OC use and breast or cervical cancer has not been established. Combination OCs may decrease ovarian and endometrial cancer risk. Irregular bleeding patterns associated with NORPLANT SYSTEM use could mask cervical or endometrial cancer symptoms.

5. *Hepatic Tumors* — Hepatic adenomas are associated with combination OC use; estimated incidence is 3 events per 100,000 users per year. Risk increases after 4 or more years of use. Hepatic adenomas are benign but may rupture and cause death through intra-abdominal hemorrhage.

6. *Ocular Lesions* — Retinal thrombosis is associated with OC use and is believed to be related to the estrogen component. However, NORPLANT SYSTEM capsules should be removed if there is unexplained partial or complete vision loss; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Undertake appropriate diagnostic and therapeutic measures immediately.

7. *Use Before or During Early Pregnancy* — Extensive epidemiological studies reveal no increased risk of birth defects when OCs are used prior to pregnancy. Studies also do not suggest a teratogenic effect when taken inadvertently during early pregnancy. No evidence suggests that risk with NORPLANT SYSTEM use is different.

8. *Gallbladder Disease* — Early studies reported an increased lifetime relative risk of gallbladder surgery in OC or estrogen users. More recent studies, however, indicate that the relative risk of gallbladder disease with OC use may be minimal; this may be related to use of OCs with less estrogen and progestin content.

Precautions

GENERAL:

1. *Physical Examination and Follow-up* — A complete medical history and physical examination should be taken prior to implantation or reimplantation of NORPLANT SYSTEM capsules and at least annually during its use. Exams should include special reference to the implant site, blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. Rule out malignancy in cases of undiagnosed, persistent or recurrent abnormal vaginal bleeding. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. *Carbohydrate Metabolism* — Altered glucose tolerance is found in some combination and progestin-only OC users. Effects of NORPLANT SYSTEM on carbohydrate metabolism appear minimal. Observe diabetic and prediabetic patients carefully while using the NORPLANT SYSTEM. Follow women being treated for hyperlipidemias closely if using the NORPLANT SYSTEM. Some progestins may elevate LDL and may render control of hyperlipidemias more difficult. (See **Warnings**.)

3. *Liver Function* — Consider removing capsules if jaundice develops. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. *Fluid Retention* — Steroid contraceptives may cause some degree of fluid retention. Prescribe with caution, and careful monitoring, in patients with conditions possibly aggravated by fluid retention.

5. *Emotional Disorders* — Consider removing capsules if significant depression occurs since the symptom may be drug-related. Observe carefully those with history of depression and consider removal if depression recurs to a serious degree.

6. *Contact Lenses* — Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. *Insertion and Removal* — Insertion is advised during the first 7 days of the cycle or immediately following abortion to insure that the woman is not pregnant and to assure contraceptive effectiveness during first cycle of use. Capsules may be inserted at any time during the cycle provided pregnancy has been excluded and a nonhormonal contraceptive method is used for the remainder of the cycle. Insertion is not recommended before 6 weeks postpartum in breast-feeding women. Follow insertion and removal instructions closely. Healthcare professionals are strongly advised to be instructed in the procedures before they attempt them. Proper insertion just under the skin facilitates removals; proper insertion and removal should result in minimal scarring. If all capsules cannot be removed at first attempt, attempt removal later when the site has healed. Bruising may occur at implant site during insertion or removal. Hyperpigmentation may occur over implant site but is usually reversible following removal. **See Full Prescribing Information for Detailed Insertion/Removal Instructions.**

8. *Infections* — Implant site infection has been uncommon (0.7%); aseptic technique and proper insertion/removal reduces possibility of infection. Institute treatment if infection occurs; remove capsules if infection persists.

9. *Expulsion* — Expulsion of capsules was uncommon; frequency increased when capsule placement was extremely shallow, was too close to incision, or when infection was present. Replace expelled capsule with new sterile capsule. Treat and cure any infection before replacement Contraceptive efficacy may be inadequate with fewer than 6 capsules.

10. *Provisions for Removal* — Advise women that capsules may be removed at any time for any reason. Personnel instructed in removal technique should perform removal on request or at the end of 5 years of usage. Upon removal, dispose of capsules in accordance with Centers for Disease Control Guidelines for biohazardous waste.

DRUG INTERACTIONS: Reduced efficacy (pregnancy) in NORPLANT SYSTEM users has been reported when phenytoin or carbamazepine were used concomitantly. Warn NORPLANT SYSTEM users of possible decreased efficacy with use of related drugs.

DRUG/LABORATORY TEST INTERACTIONS: 1. Sex-hormone-binding globulin concentrations are decreased. 2. Thyroxine concentrations may be slightly decreased and triiodothyronine uptake increased.

CARCINOGENESIS: See **Warnings** section and Full Prescribing Information.

PREGNANCY: Pregnancy Category X. See **Warnings** section and Full Prescribing Information.

NURSING MOTHERS: See **Warnings** section and Full Prescribing Information.

INFORMATION FOR THE PATIENT: See Patient Labeling. Provide copy of patient labeling to the patient. Advise patients that Prescribing Information is available upon request. Inform prospective users of risks and benefits associated with NORPLANT SYSTEM use, with other forms of contraception, with no contraception, and about insertion/removal procedures. Informed consent from all patients may be desired in light of techniques involved with insertion and removal.

Adverse Reactions

The following have been associated with the NORPLANT SYSTEM during first year of use: many bleeding days or prolonged bleeding (27.6%); spotting (17.1%); amenorrhea (9.4%); irregular (onsets of) bleeding (7.6%); frequent bleeding onsets (7.0%); scanty bleeding (5.2%); pain or itching near implant site - usually transient - (3.7%); infection at implant site (0.7%); removal difficulties affecting subjects - based on 849 removals - (6.2%).

Controlled clinical studies suggest that the following, occurring during the first year, are probably associated with NORPLANT SYSTEM use: headache; nervousness; nausea; dizziness; adnexal enlargement; dermatitis; acne; change of appetite; mastalgia; weight gain; hirsutism, hypertrichosis and scalp-hair loss. The following were reported with a frequency of 5% or greater during the first year and possibly may be related to NORPLANT SYSTEM use: breast discharge; cervicitis; musculoskeletal pain; abdominal discomfort; leukorrhea; vaginitis.

Overdosage

Overdosage may cause fluid retention with its associated effects and uterine bleeding irregularities.

Dosage and Administration

The NORPLANT SYSTEM consists of six Silastic® capsules, each containing 36 mg of the progestin levonorgestrel. The total administered (implanted) dose is 216 mg. Implantation of all six capsules should be performed during the first 7 days of the onset of menses by a healthcare professional instructed in the NORPLANT SYSTEM insertion technique. Insertion is subdermal in the midportion of the upper arm about 8 to 10 cm above the elbow crease. Distribution should be in a fanlike pattern, about 15 degrees apart, for a total of 75 degrees. Proper insertion will facilitate later removal. **(See Full Prescribing Information for Detailed Insertion/Removal Instructions.)**

Accuracy of frozen-section diagnosis at surgery in clinical stage I and II endometrial carcinoma

Jae Uk Shim, MD,[a] Peter G. Rose, MD,[a] Frank R. Reale, MD,[b] Henry Soto, MD,[c] Won K. Tak, MD,[d] and Richard E. Hunter, MD[a]

Worcester, Massachusetts

OBJECTIVES: The purpose of our study was to determine if frozen section accurately identifies certain poor prognostic pathologic factors in endometrial carcinoma that are known to be associated with pelvic and paraaortic nodal metastasis, including deep myometrial invasion, poorly differentiated tumor, cervical invasion, adnexal involvement, and poor histologic type.

STUDY DESIGN: The frozen-section pathologic results of 199 patients with clinical stage I and II endometrial cancer were retrospectively compared with permanent-section pathologic findings.

RESULTS: The depth of myometrial invasion (superficial third vs deep two thirds) was accurately determined by frozen-section diagnosis at surgery in 181 of 199 cases (91.0%). The sensitivity of frozen-section diagnosis for deep myometrial invasion was 82.7%, and the specificity was 89.1%. The following tumor characteristics were accurately determined on frozen section at surgery: poorly differentiated tumor (95.0%), cervical invasion (94.0%), adnexal involvement (98.5%), and histologic type (94.0%). Frozen section underestimated deep myometrial invasion in 17.3% of patients with this characteristic and poorly differentiated tumor in 26.3% when compared with permanent-section diagnosis. In patients with unfavorable histologic types, papillary serous and adenosquamous carcinomas were the most commonly misdiagnosed histologic types by frozen section at surgery (70.6%). However, when the preoperative curettage pathologic findings were included, these inaccuracies in tumor grade and histologic type dropped to 15.8% and 35.3%, respectively. Only 13 of 199 patients (6.5%) were not correctly identified by frozen section at surgery as having poor prognostic pathologic features.

CONCLUSION: Frozen section diagnosis at surgery is an important procedure that enables the surgeon to identify patients at high risk for pelvic and paraaortic nodal metastasis. (Am J Obstet Gynecol 1992;166:1335-8.)

Key words: Frozen section, endometrial carcinoma, surgical pathology

In the last four decades endometrial carcinoma has become the nation's most common invasive malignant tumor of the female genital tract. Approximately 33,000 new cases with 5500 deaths are estimated for 1991 in the United States.[1] The combination of total abdominal hysterectomy and bilateral salpingo-oophorectomy is the most common treatment of endometrial carcinoma. Pelvic and paraaortic nodal involvement is associated with certain pathologic findings, including deep myometrial invasion, poorly differentiated tumor, cervical invasion, adnexal involvement, and certain poor histologic types.[2] Postoperative adjuvant radiotherapy is usually recommended for patients with these unfavorable prognostic factors.[3, 4] The factors that affect the prognosis and treatment of endometrial carcinoma, including the depth of myometrial invasion, cervical invasion, adnexal involvement, and retroperitoneal lymph node metastasis, cannot be evaluated clinically before surgery or by fractional curettage. Furthermore, preoperative clinical staging differs from surgical staging in 20% to 50% of cases.[5, 6] Because of the prognostic importance of operative pathologic findings, in 1988 the Oncology Committee of the International Federation of Gynecology and Obstetrics adopted a surgical staging method for endometrial carcinoma. Intraoperative determination of the presence of poor prognostic factors may identify those patients at high risk for pelvic and paraaortic nodal involvement.

We retrospectively reviewed 199 cases of endometrial carcinoma to determine the accuracy of frozen section by comparing the frozen-section diagnosis with the permanent-section diagnosis. The preoperative curettage results were then combined with frozen-section findings to assess their effect on the accuracy of identifying these poor prognostic pathologic features.

Material and methods

Five hundred forty-one patients with clinical stage I and II endometrial carcinoma were treated at The University of Massachusetts Medical Center (n = 368) and Saint Vincent's Hospital (n = 173), from January 1983 to March 1991. Excluded from analysis were patients who were treated with radiation alone, who were found at surgery to have extrapelvic disease, who did not have frozen sections performed at the time of surgery, or who were referred after hysterectomy; thus 199 cases were available for review. The depth of myometrial invasion, tumor grade, cervical invasion, adnexal involvement, and histologic type were determined by frozen-section diagnosis at surgery. Immediately on its receipt at the frozen-section laboratory, the uterus was opened and the endometrial surface was examined for irregularities of contour and color. Transverse, full-thickness slices were made through the wall of the uterus at 2 to 3 mm intervals for gross inspection. Frozen sections were performed on the areas of deepest tumor extension selected by gross examination. Frozen sections were also performed on the endocervix in patients with a prior positive endocervical curettage or if indicated by gross pathologic findings. The number of frozen sections per uterus varied from one to four according to the gross findings. Care was taken to include both the endometrial surface and the serosal surface in each frozen section. Occasionally, because of the marked thickness of the uterine wall two contiguous sections were required to include both inner and outer surfaces. Frozen and permanent sections were compared with respect to depth of myometrial invasion, tumor grade, cervical invasion, adnexal involvement, and histologic type. Curettage specimens were reviewed for tumor grade and histologic type. Statistical analysis was performed with the Mehta exact test for homogeneity on Egret software (Statistics and Epidemiology Research Corp., Seattle).[7]

Results

Among the 199 study patients, disease was classified as clinical stage I in 164 (82.4%) and as clinical stage II in 35 (17.6%). The patient's ages ranged from 25 to 86 years with a median age of 61.7 years. One hundred three of the patients (51.8%) had one or more of the poor prognostic pathologic features.

The depth of myometrial invasion (superficial third versus deep two thirds) was accurately diagnosed by frozen section at surgery in 181 of 199 patients (91.0%). In 14 patients deep myometrial invasion was missed (middle third invasion, n = 11; deep third invasion, n = 3). In four patients deep myometrial invasion was overdiagnosed (middle-third invasion, n = 4) (Table I). The sensitivity of frozen-section diagnosis for deep myometrial invasion was 82.7% and the specificity was 89.1%. The accuracy was similar for clinical stage I and stage II cases: stage I, 148 of 164 (90.2%); stage II, 33 of 35 (94.3%). When analyzed by tumor grade, the accuracy of the depth of myometrial invasion by frozen-section diagnosis increased as the tumor grade became more poorly differentiated. The depth of invasion was accurately determined in 88.5%, 91.0%, and 95.3% of grades 1, 2, and 3, respectively. However, this difference was not statistically significant (p = 0.258).

The presence or absence of poorly differentiated tumor was correctly determined by frozen section at surgery in 189 of 199 patients (95.0%). Individual tumor grades were accurately diagnosed on frozen section in grade 1, 2, and 3 tumors in 61 of 80 (76.3%), 44 of 73 (60.3%), and 28 of 38 (73.7%) patients, respectively. Poorly differentiated tumor was overdiagnosed in two patients and missed in 10 patients (Table II). When the curettage pathologic results were combined with the frozen-section diagnosis, the frequency of undiagnosed poorly differentiated tumor decreased from 26.3% to 15.8%.

The presence or absence of cervical invasion was correctly diagnosed by frozen section at surgery in 187 of 199 patients (94.0%). Thirty-two patients with clinical stage I disease (19.5%) were found to have cervical invasion (surgical stage II). This was correctly identified on frozen section at surgery in 71.9% of cases. Of 35 patients with clinical stage II, cervical invasion was diagnosed on permanent section in 19. In 16 of these patients (84.2%) the stage of disease was correctly diagnosed by frozen section.

The presence or absence of adnexal involvement was correctly diagnosed by frozen section in 196 of 199

Table II. Correlation of tumor grade between frozen-section diagnosis and permanent-section diagnosis in 199 patients with stage I and II endometrial carcinoma

Frozen-section diagnosis	*Permanent-section diagnosis*			
	No tumor	*Grade 1*	*Grade 2*	*Grade 3*
No tumor	8	14	5	0
1	0	61	22	0
2	0	5	44	10
3	0	0	2	28

patients (98.5%). Twenty-one patients (13.8%) with clinical stage I and II disease had adnexal involvement on permanent section; in 18 (85.7%) of these were detected by frozen section.

Frozen section correctly diagnosed the histologic type in 187 of 199 patients (94.0%). Papillary serous and adenosquamous cell carcinoma were the most common histologic types that were inaccurately diagnosed by frozen section (70.6% of cases). However, when the curettage histologic diagnosis was included, the inaccuracy dropped to 35.3%. Among eight patients with papillary serous carcinoma only three had frozen section at surgery demonstrating a serous histologic type. The addition of curettage histologic results identified 75.0% of cases.

Overall, in 186 of 199 patients (93.5%), the correct diagnosis was made by frozen section at surgery with respect to the status of poor prognostic factors. Thirteen of 103 patients (12.6%) had poor prognostic factors that were not identified at frozen section; 10 had deep myometrial invasion, two had poorly differentiated tumor, and one had a papillary serous histologic type.

Comment

In the current study we compared frozen-section with permanent-section pathologic diagnoses in patients with clinical stage I and II endometrial carcinoma. The goal of frozen section is to identify patients at high risk for pelvic and paraaortic nodal metastasis. Five poor pathologic prognostic factors were evaluated: deep myometrial invasion, poorly differentiated tumor, cervical invasion, adnexal involvement, and certain histologic types. Previous studies have included only patients with clinical stage I disease. However, the endocervical curettage frequently gives false-positive results; therefore patients with clinical stage II disease were included in this analysis.[8]

In clinical stage I and II endometrial carcinoma, frozen section at surgery correctly diagnosed deep myometrial invasion in 91.0%. Malviya et al.[9] reported that frozen section accurately predicted the depth of myometrial invasion in 96.5% of 55 patients with clinical stage I endometrial carcinoma. Similarly, Fanning et al.,[10] studying frozen section in 216 cases of clinical stage I endometrial carcinoma, reported an accuracy for the depth of invasion of 95.0%. Although our data are similar to the previous reports, the accuracy is slightly less. One possible explanation for this may be the fact that multiple pathologists cover the frozen-section service in our hospitals in contrast to a single gynecologic pathology specialist.

In this study the accuracy was slightly greater for clinical stage II and cases with grade 3 curettage histologic results. Creasman et al.[2] reported that as tumor grade becomes less differentiated there is a greater tendency for deep myometrial invasion. These findings are consistent with an increased accuracy of frozen-section diagnosis at surgery in patients with more extensive uterine disease. However, Goff and Rice,[11] studying gross examination for determining the depth of myometrial invasion, reported a decrease in sensitivity as the grade of tumor increased.

Frozen section at surgery correctly diagnosed the presence of poorly differentiated tumor in 95.0% of cases of clinical stage I and II endometrial carcinoma. The previous reports by Malviya et al.[9] and Fanning et al.[10] in clinical stage I endometrial carcinoma were very similar (94.5% and 96.0%, respectively). The separation into three tumor grades by frozen section is less accurate than simply the detection of the presence of poorly differentiated tumor.

Frozen section at surgery accurately diagnosed the presence of cervical invasion in 94.0%. Fanning et al.[10] reported that cervical invasion was accurately diagnosed in 96.0% by intraoperative frozen section in clinical stage I endometrial carcinoma. In contrast, Malviya et al.[9] reported that frozen section at primary surgery predicted cervical invasion in only 66.0% of cases of clinical stage I endometrial carcinoma.

In our study frozen section at surgery accurately diagnosed the presence of adnexal involvement in 98.5%. Fanning et al.[10] reported an accuracy of 98.0% for adnexal involvement detected by intraoperative frozen section in clinical stage I endometrial carcinoma.

At surgery the correct histologic type was diagnosed in 94.0% of cases by frozen section, and papillary serous and adenosquamous carcinomas were the histologic types that were frequently misdiagnosed. Fanning et al.[10] reported that histologic type was accurately diag-

nosed by intraoperative frozen section in 90.0%. They also reported that adenosquamous carcinoma was the most common histologic type inaccurately diagnosed by intraoperative frozen section. However, in the current report the sensitivity for certain unfavorable histologic types increased from 29.4% to 64.7% when curettage pathologic findings were included.

Gross examination of the uterus for determination of deep myometrial invasion instead of frozen-section pathologic analysis has been reported by previous authors.[11, 12] However, the sensitivity of this procedure is only 71.0%, which is significantly less accurate than frozen-section diagnosis at surgery.[12]

Alternatively, other clinical studies may be used preoperatively to determine the presence of one or more of these poor prognostic findings. Gordon et al.[13] and Cacciatore et al.[14] independently reported that the depth of myometrial invasion was correctly predicted by ultrasonography in 79.0% and 80.0% of clinical stage I endometrial carcinomas, respectively. In a report from Obata et al.[15] intrauterine ultrasonography accurately predicted the depth of myometrial invasion in 81.3% of cases of clinical stage I endometrial carcinoma. Gordon et al.,[13] Hericak et al.,[16] and Chen et al.[17] each reported that in clinical stage I endometrial carcinoma magnetic resonance imaging accurately predicted deep myometrial invasion in 71.0%, 82.0%, and 94.0% of cases, respectively. Even though different imaging techniques (ultrasonography, magnetic resonance imaging, and intrauterine ultrasonography) are able to determine preoperatively the depth of myometrial invasion, frozen section at surgery is a more accurate method. Furthermore, these clinical techniques are unable to detect pathologic features such as poorly differentiated tumor, certain unfavorable histologic types, and occult adnexal involvement.

At our institution, after abdominal exploration, cytologic sampling, and palpation and removal of suspicious pelvic and paraaortic lymph nodes, an extrafascial hysterectomy and a bilateral salpingo-oophorectomy are performed. Patients with frozen-section diagnosis of no or superficial myometrial invasion, grade 1 or 2 carcinoma, no cervical invasion, and no adnexal involvement are considered at low risk for nodal metastasis, and lymphadenectomy is not performed unless the curettage had previously demonstrated grade 3 or an unfavorable histologic type. By avoiding lymphadenectomy in such patients, the risk of operative complications, such as hemorrhage, lymphocyst formation, ureteral and vascular injuries, and lengthy operating time were reduced. In contrast, patients with frozen-section diagnosis of deep myometrial invasion, grade 3 carcinoma, cervical invasion, or adnexal involvement are considered at high risk for metastasis to the nodes and selective pelvic and paraaortic lymphadenectomy is performed. Failure to perform lymphadenectomy in patients at high risk for nodal metastasis may result in underdiagnosis of extrauterine disease, subsequently leading to inadequate therapy. This study confirms the accuracy of frozen section, particularly in combination with the curettage findings, in delineating a patient group that is at high risk for lymph node metastasis.

Hospitalization for pregnancy complications, United States, 1986 and 1987

Adele L. Franks, MD, Juliette S. Kendrick, MD, David R. Olson, PhD, Hani K. Atrash, MD, MPH, Audrey F. Saftlas, PhD, MPH, and Mary Moien, MS
Atlanta, Georgia

OBJECTIVE: The purpose of our analysis was to provide a national overview of the magnitude of the public health burden associated with inpatient care for pregnancy complications.
STUDY DESIGN: We analyzed data from the National Hospital Discharge Survey for 1986 and 1987. We calculated ratios of hospitalizations for pregnancy complications for every 100 hospitalizations involving a birth. Standard errors for these ratios were calculated with RATIOEST, and relative ratios with 95% confidence intervals were calculated for subgroups of interest.
RESULTS: We found that for every 100 hospitalizations involving a birth, there were 22.2 nondelivery hospitalizations for pregnancy complications (14.6 antenatal complications, 7.6 pregnancy loss complications). These ratios were higher for black than for white women (relative ratio 1.4, 95% confidence interval 1.2 to 1.6). The effects of marital status, age, and insurance coverage differed between black and white women, and mean length of stay was longer for black than for white women.
CONCLUSION: Hospitalization for pregnancy complications is far more common than is widely appreciated and is more frequent among black than white women. (AM J OBSTET GYNECOL 1992;166: 1339-44.)

Key words: Maternal morbidity, pregnancy complications, hospitalization, race

Pregnancy is a common condition; in the United States there are now approximately 4 million deliveries,[1] 1.35 million induced abortions,[2] 88 thousand ectopic pregnancies,[3] and, on the basis of recent estimates of early pregnancy loss,[4] likely many more than 1 million spontaneous abortions—adding up to more than 6 million pregnancies per year. Yet there is insufficient information on the epidemiologic characteristics of pregnancy complications or on the magnitude of the public health burden they create. We lack knowledge about which complications of pregnancy cause the most morbidity and about what characteristics of women or their health care are associated with higher risks of complications. This article provides an overview of pregnancy complications involving hospitalization in the United States.

Methods

We analyzed data collected by the National Center for Health Statistics by means of the annual National Hospital Discharge Survey. The design and methods of the National Hospital Discharge Survey have been previously published.[5] The survey uses a sample of nonfederal, short-stay hospitals in the United States, stratified by geographic location and hospital size. From approximately 400 participating hospitals, a sample of approximately 200,000 inpatient records are selected each year and weighted to represent >30 million hospitalizations nationally. From each selected record, information on patient characteristics, medical diagnoses, and surgical procedures is abstracted from the face sheet of the hospital chart. As many as seven discharge diagnoses and four procedures are coded according to the International Classification of Diseases, Ninth Revision, Clinical Modification.[6]

We based our analysis on hospitalizations of women with complications of pregnancy occurring from 1986 through 1987, the most recent years for which data were available. It was necessary to combine 2 years of data to provide a sufficient number of black women for race-specific analyses. Because there were insufficient numbers of women of other races, we restricted race-specific analyses to white and black women. Individual women could have been hospitalized more than once during a pregnancy; it is therefore possible that for some women more than one hospitalization could be represented in our analysis. Therefore this report is based on hospitalization episodes rather than on individual women. The numbers of hospitalizations are rounded to the nearest hundred for presentation.

We selected for analysis hospitalizations in which In-

Table I. Number* of pregnancy-related hospitalizations, type and year, 1986 and 1987 National Hospital Discharge Survey

Hospitalization type	*1986*	*1987*	*Total*
Antenatal	533,900	583,400	1,117,300
Pregnancy loss	302,500	278,600	581,100
Delivery	3,760,000	3,907,500	7,667,500

*Rounded to nearest hundred.

ternational Classification of Diseases, Ninth Revision, Clinical Modification codes 630.0 through 676.9 (complications of pregnancy, childbirth, and puerperium) or V27.0 through V27.9 (outcomes of delivery) appeared as diagnoses. There were 9,516,000 hospitalizations with these codes in 1986 through 1987.

Our primary interest was hospitalizations during pregnancy that were not associated with induced abortion or delivery. Because hospitalizations that included an induced abortion or delivery could have incidental complications diagnosed that alone would not require hospitalization, including them would lead to overestimating the number of hospitalizations required for pregnancy complications. Therefore we excluded hospitalizations that (1) occurred postpartum (62,400), (2) involved an induced abortion (87,900), and (3) included a delivery (7,667,500). These exclusions left roughly 1,698,000 nondelivery hospitalizations related to complications of pregnancy for our analysis. We used the delivery hospitalizations to calculate a hospitalization ratio (as described later).

We divided the nondelivery hospitalizations into two main categories for analysis: antenatal hospitalizations and hospitalizations related to pregnancy loss. Antenatal hospitalizations were those in which a woman entered the hospital with a complication of pregnancy and was still pregnant when she was discharged. Hospitalizations related to pregnancy loss were those in which a woman experienced a complication of pregnancy and left the hospital no longer pregnant and without delivering a live or stillborn fetus (provided that no induced abortion procedure was performed during the hospital stay).

We used information gathered at the time of admission to classify patients according to whether they had private health insurance. Those whose expected source of hospital payment consisted of any form of private or commercial insurance were considered to have private insurance, whereas those with expected government reimbursement or self-payment were considered not to have private insurance. Those with other designations (<5% of records) were excluded from this classification.

We examined disease burden as a ratio of hospitalizations for pregnancy complications per 100 hospitalizations involving delivery of a stillborn or live infant. Standard errors for ratios were calculated with RATIOEST,[7] a statistical procedure that takes into account the design features of complex multistage surveys such as the National Hospital Discharge Survey. Relative ratios were calculated to compare the ratios of particular subgroups, and 95% confidence intervals for these relative measures were calculated with the Taylor series linearization method.[8] All significantly elevated or reduced relative ratios were directly standardized in a univariate fashion for every other significant factor, to the distribution of that characteristic among all deliveries. The only standardized measures that differed from the nonstandardized did so in a direction further from the null. Therefore for statistical purposes the nonstandardized ratios are reported here; in a few instances these represent a slight underestimate of the true effect.

Mean length of stay and its standard error was calculated for each race with SESUDAAN.[9] We used the *t* test to evaluate differences in mean length of stay between races.

Results

In 1986 and 1987 there were an average of 849,200 pregnancy-related hospitalizations per year that did not involve a delivery, an induced abortion procedure, or a postpartum diagnosis; this yielded an overall ratio of 22.2 hospitalizations for pregnancy complications per 100 delivery hospitalizations, 14.5 antenatal hospitalizations and 7.6 pregnancy loss hospitalizations per 100 deliveries (Table I). Black women had a 40% higher ratio of hospitalizations (both antenatal and pregnancy loss) per 100 deliveries than did white women (Table II). Other demographic risk factors analyzed appeared to show different patterns between black and white women as well. Therefore we stratified all further analyses by race.

Antenatal hospitalization. Table III presents antenatal hospitalization ratios by selected characteristics. The ratios varied with age and race; for white women the ratio decreased with age whereas for black women the trend was in the opposite direction. Among the women for whom marital status was known, 20.5% of white women and 64.3% of black women were unmarried at the time of hospitalization. The antenatal hospitalization ratio was significantly higher among un-

*Excluded are 2000 hospitalizations of white women and 900 hospitalizations of black women with age unknown and 1400 hospitalizations of white women and 2500 of black women with age <15 or >44 years.
†Excluded are 148,900 hospitalizations of white women and 38,900 hospitalizations of black women with marital status unstated.
‡Excluded are 23,800 hospitalizations of white women and 9000 hospitalizations of black women with unclassifiable insurance status.

married than among married white women. Marital status was not a differentiating factor among black women. Similarly, among the women for whom health insurance status was classifiable, 36.5% of white women and 66.1% of black women were uninsured. The antenatal hospitalization ratio was significantly increased among uninsured white women but not among uninsured black women.

The most prevalent among all listed diagnoses were preterm labor (344,000), genitourinary infection (112,600), early pregnancy hemorrhage (102,000), excessive vomiting during pregnancy (96,600), pregnancy-induced hypertension (76,100), and diabetes mellitus (62,200). Fig. 1 shows the proportion of all antenatal hospitalizations that included these diagnoses. Among these diagnoses, the mean length of stay was longest for diabetes mellitus (4.4 days for whites, 5.5 days for blacks) and shortest for preterm labor (1.8 for whites, 2.4 for blacks). For all antenatal diagnoses combined the mean length of stay for blacks was 3.3 days, significantly longer than the 2.5 days for whites ($p < 0.01$). Overall, antenatal hospitalizations accounted for 2,948,700 hospital days for the period 1986 through 1987.

Pregnancy loss hospitalizations. Table IV presents pregnancy loss hospitalization ratios by selected characteristics. In general, the ratios increased with age for both whites and blacks. For white women the ratio was increased among the unmarried, whereas for black women marital status was not a differentiating factor.

The most prevalent among all listed diagnoses were spontaneous abortion (138,400), ectopic pregnancy (137,700), unspecified abortion (135,100), and missed abortion (51,780). Fig. 2 shows the proportion of all pregnancy loss hospitalizations that included these diagnoses. The mean length of stay was longest for ectopic pregnancy (3.6 days for whites and 4.7 days for blacks). For all pregnancy loss diagnoses combined, the mean length of stay for blacks was 2.7 days, significantly longer than the 1.9 days for whites ($p < 0.01$). Overall, pregnancy loss hospitalizations during the 2-year period accounted for 1,199,500 hospital days.

Comment

For the period 1986 through 1987 there were approximately 850,000 hospitalizations each year to manage pregnancy complications independent of a delivery, an induced abortion procedure, or a postpartum condition. For every 100 delivery hospitalizations there were over 22 hospitalizations for pregnancy complications. We consider this an underestimate of the actual magnitude of the problem of hospitalization for pregnancy morbidity, because many deliveries occur during hospitalizations involving unsuccessful or extended managment of complications (e.g., preterm labor, pregnancy-induced hypertension). As described above, these hospitalizations were excluded from the numerator in our analysis to avoid counting incidental complications that alone would not have required hospitalization.

Both for hospitalization for antenatal conditions and

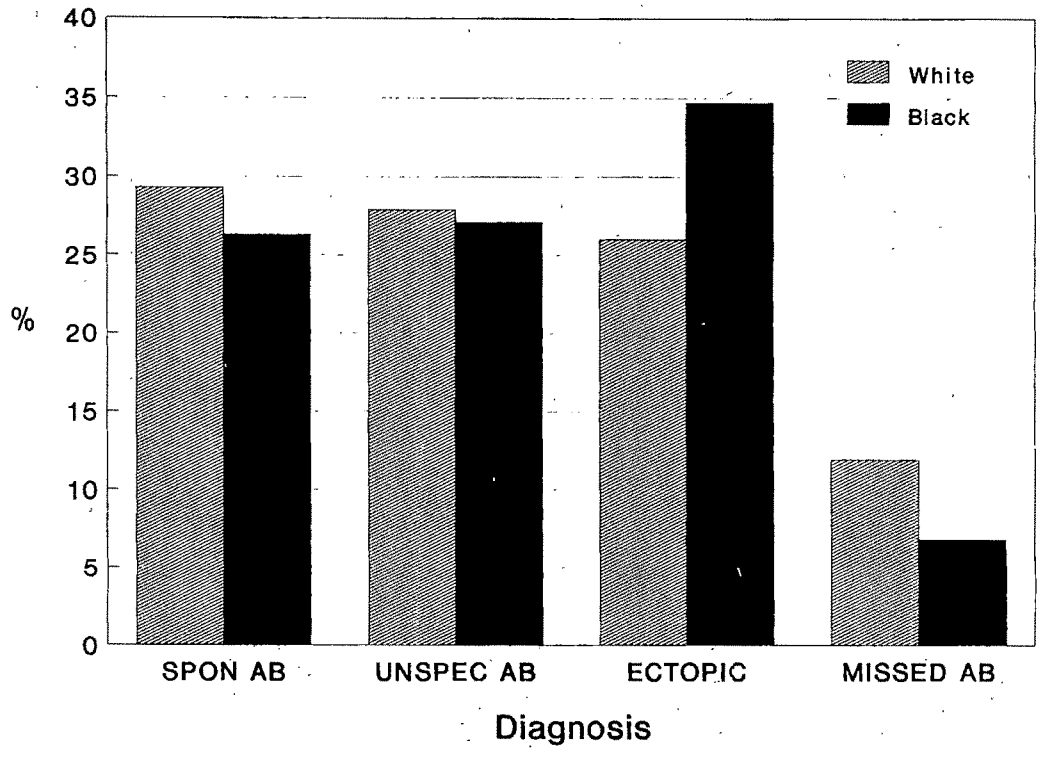

Fig. 2. Percentage of pregnancy loss hospitalizations with leading diagnoses. *SPON AB*, Spontaneous abortion; *UNSPEC AB*, unspecified abortion; *ECTOPIC*, ectopic pregnancy; *MISSED AB*, missed abortion. See text for explanation.

for pregnancy loss management, blacks had a 40% greater ratio of hospitalizations per 100 deliveries than did whites. Potential explanations for this race difference include greater incidence of pregnancy complications among blacks, greater likelihood of inpatient versus outpatient care, greater likelihood of multiple hospitalizations during pregnancy, or greater severity of clinical presentation. The latter two hypotheses are consistent with the fact that black women tend to receive less adequate prenatal care than white women.[10-12] The reasons for this racial discrepancy are subject to much debate and include the possibility of less access to care, negative attitudes toward the medical care system, and other barriers to care.[13, 14] Lacking the availability of a trusted health professional to consult about problems, black women may be more likely to defer care until symptoms become severe enough to demand immediate attention. Moreover, the quality of care and the likelihood of medical intervention received by blacks is known to differ from that received by whites in several areas, including cardiology, renal transplantation, and general internal medicine.[15-21] If less intervention occurs as well for blacks in prenatal care, problems may be more likely to progress to a later stage, requiring hospitalization, perhaps repeatedly.

At the extremes of severity, if black women are seen with more advanced pregnancy complications than white women, it would be expected that a greater proportion of black women would undergo delivery as the only recourse for treatment of advanced stages of conditions such as preterm labor or pregnancy-induced hypertension. If such were the case, our finding of an elevated antenatal hospitalization ratio among black women would represent an underestimate of the actual race difference, because delivery hospitalizations were excluded from the numerator in our analyses for reasons given above.

The fact that being unmarried was associated with higher antenatal and pregnancy loss hospitalization ratios for white women but not black women is not surprising. Among white women pregnancy in the social setting of being unmarried may be associated with substantial social problems that affect both interaction with the health care system and the presence of risk factors for complications. Among black women, marital status may not be a similar indicator of social circumstances, because the majority of births to black women occur among those who are unmarried[22]; thus pregnancy outside of marriage may not serve as a marker of special risk status among black women.

The discrepant findings regarding the association of health insurance with antenatal hospitalization ratios for black and white women may have a similar explanation. Although most white women have private health insurance, the reverse is true for black women. Thus the lack of health insurance may be a marker for

adverse social circumstances among white women, although not providing such a marker of special risk status among black women. It should be noted that the hospitalization ratios for insured and uninsured black women were each higher than the ratio for uninsured white women.

The limitations of using hospital discharge data for epidemiologic studies are well known. Differentiating multiple admissions of the same patient from hospitalizations of different individuals is often impossible because personal identifying information is not available. For this reason we are unable to determine whether the race difference in hospitalization ratios is attributable to a different frequency of multiple hospitalizations for the same women or to different hospitalization rates in pregnancy. However, at least in the case of the race difference in pregnancy loss hospitalizations, multiple admissions are an unlikely explanation; these conditions are almost always one-time events within a single pregnancy.

The paucity of information in hospital discharge data also limits their utility. Information on pregnancy history, income, education, occupation, life stresses, disease severity, adequacy of prenatal care, and nature of attempted outpatient management are of great importance for understanding hospitalization for complications of pregnancy, but these data were not available.

Nonetheless, existing hospital discharge data are useful for quantifying the magnitude of the public health burden of certain types of health problems, for drawing attention to the importance of more detailed research, and for providing some direction for future studies. This analysis provides an overview of the considerable burden of pregnancy morbidity on hospital services. Pregnancy complications required, on average, over two million hospital days of care per year in 1986 and 1987 and cost over one billion dollars per year in hospital charges alone (on the basis of an average hospital cost of $520 per day[23, 24]). Needless to say, even our surprisingly high estimates give only an indirect indication of the burden of hospitalization on women and their families in terms of loss of productive days, family disruption, emotional anguish, and financial strain.

We thank Evelyn Finch for her invaluable assistance in data management throughout the course of this analysis and Andrew Friede, MD, MPH, for his early conceptual contributions to this project.

Buserelin acetate versus expectant management in the treatment of infertility associated with minimal or mild endometriosis: A randomized clinical trial

Luigi Fedele, MD,[a] Fabio Parazzini MD,[b] Enrico Radici, MD,[c] Luca Bocciolone, MD,[a, b] Stefano Bianchi, MD,[a] Cosetta Bianchi, ScD,[b] and Giovanni Battista Candiani, MD[a]

Milan and Bergamo, Italy

OBJECTIVE: We performed a randomized clinical trial to evaluate the efficacy of intranasal 400 μg buserelin three times daily for 6 months versus expectant management in the treatment of infertile women with pelvic endometriosis stage I or II of the revised American Fertility Society classification.

STUDY DESIGN: Seventy-one consecutive patients (mean age 32 years) were studied at the First Department of Obstetrics and Gynecology, University of Milan, and the Department of Obstetrics and Gynecology, Ospedali Riuniti, Bergamo, between February 1988 and June 1989. Thirty-five women were randomly allocated to buserelin treatment and 36 to expectant management. The baseline distribution of subjects for age, disease stage, and reproductive history was similar in the two groups. All patients were followed regularly; median follow-up was 17 months in the buserelin group and 18 months in the women given expectant management. If pregnancy did not occur within 12 months of randomization, cycles were monitored by ultrasonography and hormone measurements, and when abnormalities were detected clomiphene citrate and human chorionic gonadotropin were administered.

RESULTS: A total of 17 pregnancies were observed both in the buserelin-treated patients and in the expectant management group. The 1- and 2-year actuarial overall pregnancy rates were similar in the two groups, 30% and 61% in the former and 37% and 61% in the latter group, respectively. Spontaneous abortion occurred in five of the 17 pregnancies in the women treated with buserelin and in one of the 17 in those managed expectantly; this difference was, however, not statistically significant (χ^2_1 adjusted for disease stage and use of clomiphene citrate and human chorionic gonadotropin treatment = 3.01, $p = 0.08$). No fetal death or stillbirth was observed.

CONCLUSIONS: Our findings suggest that treatment with gonadotropin-releasing hormone agonists is unlikely to have a marked influence on the reproductive outcome of infertile women with minimal or mild endometriosis. (Am J Obstet Gynecol 1992;166:1345-50.)

Key words: Buserelin acetate, infertility, endometriosis

Pelvic endometriosis is a common gynecologic disease. Because it is often found in patients with otherwise unexplained infertility, it has been commonly implicated as a cause of infertility. Surgical ablation of endometriotic lesions is the most widely performed therapy in advanced stages, but in minimal and mild endometriosis the usual therapeutic approach is laser vaporization of the lesion or pharmacologic suppression of ovarian activity. Currently, four basic hormonal regimens are available: danazol, progestins, gestrinone, and gonadotropin-releasing hormone (GnRH) agonists.

6/1/35389

In spite of the large amount of published clinical data, there is still considerable uncertainty regarding the efficacy of these hormonal treatments for increasing conception rates in early endometriosis.[1, 2] Published series were generally small and subjects had different stages of the disease. Furthermore few randomized trials included untreated or placebo controls. In particular few data are available on the role of GnRH agonists to improve reproductive prognosis in infertile women with minimal or mild pelvic endometriosis.

In this paper we report the results of a randomized clinical trial comparing the efficacy of buserelin versus expectant management in the treatment of infertile women with pelvic endometriosis stage I or II of the revised American Fertility Society classification.[3]

Subjects and methods

Eligible patients were women aged ≤38 years who were trying to conceive and had a laparoscopically confirmed diagnosis of minimal or mild endometriosis

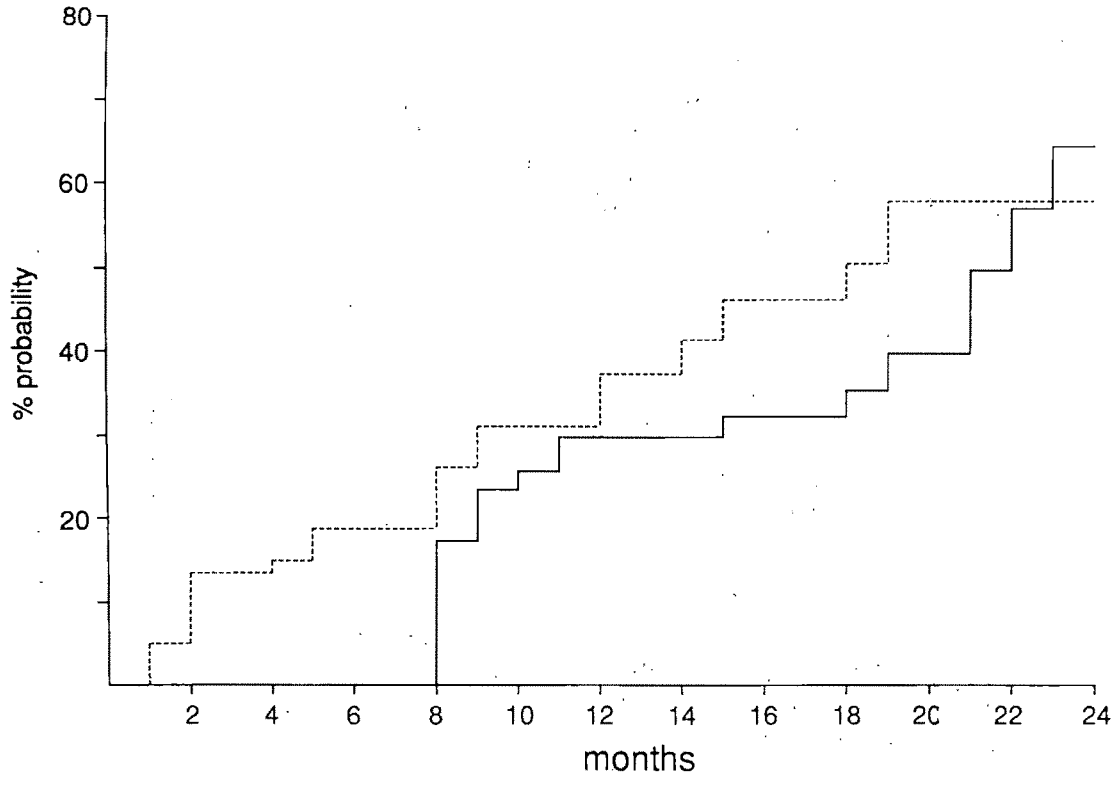

Fig. 1. Overall 24-month probability of becoming pregnant in 71 subjects with minimal or mild endometriosis according to treatment allocation, Milan, Italy, 1988 to 1990. ——, Buserelin-treated group; - - - - -, expectant management group. χ_1^2 adjusted for stage = 0.69, $p = 0.41$ for 12-month analysis; $\chi_1^2 = 0.95$, $p = 0.33$ for 24-month analysis.

(stage I or II of the revised American Fertility Society classification[3]) and otherwise unexplained infertility of ≥2 years. Women were eligible if they had normal results on standard medical and gynecologic examination and hysterosalpingogram, luteal-phase endometrial biopsy, hormone profile (two follicle-stimulating hormone, luteinizing hormone, and estradiol assays in the follicular phase and three progesterone and prolactin assays in the luteal phase), and postcoital test. Further, all partners had two semen analyses to exclude severe dyspermia (>10 × 10^6 sperm per milliliter, quantity >1.5 ml, >30% progressive motility at the third hour, >30% typical forms, absence of agglutination, and leukocyte count <2,000,000 ml). Women with a previous clinical or laparoscopic-laparotomic diagnosis of endometriosis or with any other disease that might affect fertility (for example, uterine malformation or uterine myomas) were specifically excluded from the trial. No women had had previous therapy for endometriosis or infertility. The investigators obtained approval of the protocol from their institutional review board, and each patient gave informed consent. Four eligible women refused to enter the study.

A total of 71 consecutive women observed between February 1988 and June 1989 at the First Department of Obstetrics and Gynecology, University of Milan, and Department of Obstetrics and Gynecology of Ospedali Riuniti, Bergamo, entered the study. The diagnostic laparoscopy was performed under the supervision of L.F. for cases diagnosed in Milan and E.R. for those diagnosed in Bergamo.

Patients were assigned by phone according to a computer-generated randomization list to one of the following treatments: intranasal buserelin (Suprefact, Hoechst, Milan, Italy) 400 μg three times daily for 6 months (35 subjects) and expectant management (36 subjects). If dysmenorrhea or pelvic pain occurred, the patients were asked to use naproxen sodium as first-line treatment.

All patients were examined regularly every 4 months. The median follow-up was 17 months for the patients who received buserelin and 18 months for those who did not. At each follow-up visit a standard gynecologic examination was performed and the occurrence of pregnancy recorded. If pregnancy did not occur within 12 months of randomization, cycles were monitored for

two cyles by ultrasonography and hormone measurements. In 29 women the following abnormalities, according to Eissa et al.,[4] were detected: luteinized unruptured follicle cycle (seven cases), luteal phase failure (eight cases), and asynchronous follicle cycle (14 cases). In all these cases clomiphene citrate, 100 mg/day, was given from day 3 to 7 of the cycle, and human chorionic gonadotropin (hCG), 10,000 IU, was administered intramuscularly on the basis of ultrasonographic findings. Induction of ovulation was performed until six cycles.

The present analysis is based on information obtained until June 1990. The outcome of pregnancy with the last menstrual period before June 1990 was checked and data on deliveries collected until February 1991.

Data analysis. We calculated with the actuarial method the cumulative proportion of women who became pregnant, and the curves obtained were compared by the log-rank test.[5] The event data used in the computation of the probability of becoming pregnant were the date of laparoscopy (i.e., of randomization) and the date of the last menstrual period or last follow-up visit.

Tests of statistical significance for the differences in baseline characteristics of the patients and in the frequency of spontaneous abortions on the total of observed pregnancies in relation to treatment allocation were based on the usual χ^2 value, comparing observed and expected numbers of events with the outcome of pregnancy. To allow for the potential confounding effect of stage and ovulation-induction treatment on the outcome of pregnancy, Mantel-Haenszel procedure was used.[6] When indicated, the significance in the linear trend was assessed with the Mantel test.[7]

Results

Table I shows the distribution of the patients according to age, disease stage, history of spontaneous abortion, years of infertility, and treatment allocation. The distribution for these variables was similar in both groups. All patients who entered the study actively tried to become pregnant during the study period. All the buserelin-treated patients took the drug regularly. Amenorrhea was observed in 24 subjects after 1 month of treatment and in all cases after 2 months of treatment. A total of 15 patients in the buserelin (43%) and 14 in the no-treatment group (39%) received drugs to stimulate ovulation (see Subjects and methods).

A total of 17 pregnancies was observed both in the buserelin-treated patients and in the expectant management group (Table II). Of the 34 pregnancies, 13 (seven in the buserelin and six in the no-treatment group) occurred after treatment with clomiphene citrate and hCG. The mean number of cycles in which ovulation was induced in women who conceived after the treatment with clomiphene citrate and hCG was 3.8, with no important difference between the buserelin-treated and the expectant management group.

The 12-month (i.e., before clomiphene citrate + hCG therapy) and the 24-month actuarial overall pregnancy rates were, respectively, 30% and 61% in the buserelin group and 37% and 61% in the expectant management group (χ^2_1 adjusted for stage = 0.69, p = 0.41 for 12-month analysis; χ^2_1 = 0.95, p = 0.33 for 24-month analysis; Fig. 1).

Spontaneous abortion occurred in five (29%) of the 17 pregnancies observed in the buserelin-treated group and in one (6%) of the 17 in the expectant management

Table II. Number of patients at risk and number of observed pregnancies according to month of follow-up and treatment allocation, Milan, Italy, 1988 to 1990.

group, but this difference was not statistically significant (χ^2_1 adjusted for disease stage and use of clomiphene citrate and hCG treatment = 3.01; $p = 0.08$).

Comment

This study shows that in infertile women with minimal or mild endometriosis the short-term reproductive outcome was not markedly affected by treatment with buserelin.

Before discussing these results, potential biases should be carefully considered. Our study compares the reproductive outcome in women treated with buserelin and untreated controls in a nonblinded way. However, this should not represent a problem with regard to reproductive prognosis. Considering the frequency of adverse effects related to GnRH agonist treatment, it is, in our opinion, impossible to conduct a "true" double-blind trial. As indicated in the data analysis section, we computed reproductive rates with the date of randomization as an event date. Thus when we computed the 1-year pregnancy rate patients randomized to the buserelin group had actually tried to conceive for only 6 months (because they were under treatment for the first 6 months). We chose to present our results in this way because we think that the 6 months of treatment during which the patients could not conceive should be considered in an overall risk-benefit analysis of the effect of the treatment. In any case life-table analysis performed on only the months of active attempts at conceiving (i.e., considering as starting date the date of randomization in the no-treatment group and the date of stopping treatment in the buserelin group) did not show any statistically significant differences in reproductive outcome at 6 months (data not shown). With regard to other sources of bias, all randomized patients were regularly observed, compliance with the study protocol was generally complete, and the two groups were comparable in terms of age, reproductive history, and disease stage. Another potential limitation of this study is the small sample size and hence its low statistical power. However, with this sample size we can exclude, at the usual level of a study power ($\beta = 0.20$), a double reproductive rate in the treated versus the not-treated women.

According to the study protocol, if a patient had not become pregnant 1 year from randomization, she underwent ultrasonography and endocrine monitoring of two cycles. When we detected abnormalities of folliculogenesis or ovulation as in the patterns described by Eissa et al.,[4] the patients were treated with clomiphene citrate and hCG. This situation must be considered carefully in interpreting the 2-year pregnancy rates and in the generalization of the results of the study. In this regard, the observation that ovulation induction improved fertility rates similarly in both the groups suggests that previous treatment with a GnRH agonist does not affect the efficacy of ovulation induction treatment. Of course, this study cannot evaluate the effect of ovulation induction in improving the prognosis of infertile endometriotic women. It is conceivable that endometrosis impairs folliculogenesis, and ovulation induction may overcome this obstacle, increasing the likelihood of a pregnancy.

In our treated group the abortion rate was greater than in the women given expectant management. This difference was not statistically significant, and in the absence of any biologic explanation it should be largely attributable to chance.

In spite of these potential limitations this is, to our knowledge, the first randomized study reported in the literature that compares GnRH agonist treatment of endometriosis-associated infertility with expectant management. The fertility rates obtained after buserelin treatment were comparable to those observed in

the main clinical studies published so far on the use of GnRH agonists in the treatment of endometriosis. In a large randomized multicenter study[8] comparing danazol, 800 mg/day, and intranasal nafarelin, 400 or 800 μg/day, for 6 months in 149 infertile women there were no statistically significant differences among the 12-month pregnancy rates in the three groups. The pregnancy rates were, respectively, 36%, 30%, and 52%. A randomized study comparing danazol, 600 mg/day, and intranasal buserelin, 1200 μg/day, for 6 months in about 60 patients showed 18-month cumulative pregnancy rates of, respectively, 43% and 38%.[9] The 12-month cumulative pregnancy rates in the randomized study of Dmowski et al.[10] comparing subcutaneous or intranasal buserelin with danazol were 44% and 62%, respectively. In an open study performed by Franssen et al.[11] in which buserelin, 900 μg/day, was given for 6 months the cumulative pregnancy rate after 6 months of follow-up was 32% in 22 previously infertile women.

Until now only four randomized clinical trials[12-15] comparing hormonal treatment with expectant management or placebo have had reproductive outcome as one of the end points. None of these studies reported significant differences between the treatment groups, which received danazol, gestrinone, or medroxyprogesterone acetate or were not treated. In the latter group, the cumulative pregnancy rates at 12 to 30 months were 24% and 57%, respectively.

The failure of buserelin treatment, like that of other hormonal treatments, to improve the infertility associated with minimal and mild endometriosis warrants consideration. First, evidence exists that endometriotic lesions regress after treatment with GnRH agonists,[8, 10, 11, 16] but microscopic examination of the apparently cured pelvic areas has demonstrated the persistence of ectopic endometrium[17] and mitotic activity.[18] Further, there is no evidence of the presumed relation between minimal and mild endometriosis and subfertility.[19, 20]

In conclusion, these results and those of previous studies provide evidence that treament with GnRH agonists is unlikely to have a marked influence on the reproductive outcome in infertile women with minimal or mild endometriosis.

Magnetic cell sorting and the transferrin receptor as potential means of prenatal diagnosis from maternal blood

Dorothee Gänshirt-Ahlert, PhD,[a] Monika Burschyk, MS,[a] Henk S.P. Garritsen, MD,[b] Lisa Helmer, BS,[a] Peter Miny, MD,[c] Jürgen Horst, MD,[c] Hermann P.G. Schneider, MD,[a] and Wolfgang Holzgreve, MD[a]

Münster, Germany

OBJECTIVE: We wanted to test whether the recently described method of using the transferrin receptor system for fluorescence-activated cell-sorter enrichment of nucleated red blood cells can be used for prenatal diagnosis from maternal blood.
STUDY DESIGN: Instead of the laborious, expensive fluorescence-activated cell-sorter system, we used the newly described magnetic-activated cell sorter.
RESULTS: An effective enrichment could be achieved with separation of lymphocyte subsets. With the transferrin receptor, however, the enrichment was very inefficient because of the poor specificity of the antibody itself. Even in umbilical cord blood only 25% of nucleated red blood cells were labeled as demonstrated by immunogold silver enhancement of transferrin receptor–labeled cells.
CONCLUSION: In spite of the availability of a fast and effective separation method (magnetic-activated cell sorter) the use of the transferrin receptor antigen alone is not likely to enable a reliable identification of fetal cells in maternal circulation. (Am J Obstet Gynecol 1992;166:1350-5.)

Key words: Transferrin receptor, fluorescence-activated cell sorter, magnetic-activated cell sorter, polymerase chain reaction

The occurrence of fetal nucleated cells within maternal circulation has raised hopes for a noninvasive method of prenatal diagnosis.[1-3] By application of the polymerase chain reaction, a powerful technique for amplification of specific deoxyribonucleic acid sequences from samples as small as one cell, this goal appears to be accessible. Attempts to amplify Y-specific sequences from the deoxyribonucleic acid of pregnant women have shown that the number of fetal cells in maternal circulation is extremely small, ranging within the lowest detection limit even of the polymerase chain reaction.[3] Yet the risk of contamination—a well-known limitation of the polymerase chain reaction technique—is most prevalent at the highest level of sensitivity and hence often leads to false-positive results.[4, 5]

Total cell count at different stages of the separation procedure as evaluated in a Thoma Zeiss counting cell. *MACS,* Magnetic-activated cell sorter.

*Actual cell number is higher because the cells were partially clotted during immunofluorescence staining.

This risk of contamination caused several authors to evaluate methods of enrichment of fetal leukocytes,[6] nucleated erythrocytes,[7] or trophoblast cells[8] before polymerase chain reaction analysis.

Only flow cytometry has been used to separate fetal cells, but even with the use of multiparameter fluorescence-activated cell sorters, including forward scattering, this method is still time-consuming. We therefore have investigated the usefulness of the recently developed magnetic-activated cell sorter (Milteneyi Biotec GmbH, Bergisch-Gladbach, Germany)[9] with respect to its effectiveness in enriching fetal nucleated erythrocytes; this easier and faster technique would allow a much larger volume of blood to be separated in a given time period.[9]

Fetal nucleated erythrocytes are abundant in fetal blood early in gestation, but are unlikely to be present in the blood of normal adults and express the transferrin receptor antigen on the cell surface.[10] Therefore we chose the enrichment of these cells from fetal umbilical cord blood as a suitable system to evaluate the capacity of the magnetic-activated cell sorter procedure. Before the magnetic separation the cells were sequentially labeled with a monoclonal antibody against the transferrin receptor, biotinylated goat antimouse immunoglobulin G, a fluorescent conjugate, and superparamagnetic microbeads.

Material and methods

Separation of mononuclear cells. Three milliliters of ethylenediaminetetraacetic acid–umbilical cord blood was mixed with 3 ml of buffer (0.3% trisodium citrate and 0.5% bovine serum albumin in phosphate-buffered saline solution: 0.137 mol/L sodium chloride, 0.002 mol/L potassium chloride, 0.008 mol/L sodium biphosphate, 0.0015 mol/L potassium dihydrogen phosphate, pH 7.4) layered over 3 ml of Histopaque-1077 (Sigma, München) and spun at 400*g* for 25 minutes at room temperature. The mononuclear cell layer was isolated and washed three times in buffer 1.

Immunofluorescent staining. Cells (2×10^6) were resuspended in 200 μl of buffer 2 (0.01% sodium azide, 1% bovine serum albumin in phosphate-buffered saline solution) and stained with a 1:10 dilution of anti–transferrin receptor (anti-CD71, Becton Dickinson, Heidelberg) at 4° C for 15 minutes. The cells were washed twice and stained in a 1:10 dilution of biotinylated goat antimouse immunoglobulin G (Amersham, Buckinghamshire, United Kingdom) in buffer 2 for 15 minutes at 4° C and again were washed twice.

Table III. Percentage of transferrin receptor–labeled cells in fluorescence microscopy

8	1*	0*	—

Number of brightly fluorescing cells in proportion to all cells visible under phase-contrast microscopy. One hundred cells counted. *Enrichment factor,* Transferrin receptor–positive cells in transferrin receptor–positive samples per transferrin receptor–positive cells in transferrin receptor–negative samples. *MACS,* Magnetic-activated cell sorter.

*Actual cell number is higher because cells were partially clotted during immunofluorescent staining.

After resuspension in 200 μl buffer 2, 20 μl of streptavidin–fluorescein isothiocyanate (250 μg/ml original concentration) (Boehringer, Mannheim, Germany) was added followed by an incubation at 4° C for 15 minutes. In the last step 20 μl of magnetic-activated cell sorter biotinylated microbeads (Milteneyi Biotec) that had been diluted 1:100 (vol/vol) in buffer 2 was added, and the suspension was again incubated for 5 minutes at 4° C.

To test the effectiveness of the magnetic-activated cell sorter procedure, mononuclear cells from three peripheral control blood probes were isolated by Ficoll separation and 10^7 cells were labeled with Leu-7 biotin (anti-CD57) (Becton Dickinson, Heidelberg), then with streptavidin–fluorescein isothiocyanate; after incubation of 10 minutes microbeads were added as described above.

Magnetic-activated cell sorting. The cell suspension was passed over a separation column with a magnetizable matrix that was placed into a magnetic field of extreme strength. Unlabeled cells flowed through the matrix (negative sample), and labeled cells stuck to the column and were eluted after being taken away from the magnetic field (positive sample).

Immunogold silver staining. To test the specificity of the transferrin receptor antibody staining we performed immunogold silver staining in two control umbilical cord blood samples and in peripheral blood samples of two pregnant and one nonpregnant women. Mononuclear cells were separated and stained with the anti–transferrin receptor fluorescein isothiocyanate (5 μl/10^6 cells) as described above. After two washes at 4° C in buffer 2, 2×10^6 cells were mixed with 33 μl of Auro Probe One goat antimouse immunoglobulin G (Amersham) that had been diluted 1:40 (vol/vol) in buffer 2 before and incubated at room temperature for 60 minutes. Auro Probe One is goat antimouse immunoglobulin G linked to gold particles. After two washing steps at 4° C in buffer 2, cells were suspended in buffer 2 in a concentration of 2×10^6 cells/ml, and 100 μl samples were used for cytospins. The slides were fixed for 30 seconds in fixation buffer (20 mg sodium phosphate, 100 mg potassium dihydrogen phosphate in 30 ml water, 45 ml acetone, and 25 ml 37% formaldehyde, pH 6.7), washed three times for 3 minutes in aqua bidest, and air dried overnight.

Enhancement. Silver enhancement was performed according to the suggestions of the manufacturer (Amersham). The silver enhancement time was defined to be approximately 30 minutes for this application. Cytospins were air dried overnight and differentially stained with Diff-Quick (Merz and Dade, Düdingen, CH) in order to identify specific cell populations.

Microscopy. Cytocentrifuge cell preparations were performed after the different steps of staining and the magnetic-activated cell sorter procedure. These and the blood smears obtained from whole blood were differentially stained with Diff-Quick (Merz and Dade) and investigated under a light microscope (Zeiss Orthoplan). Fluorescence microscopy was performed on a photomicroscope (Zeiss Orthoplan, Oberkochen, Germany). Cell counts at different stages of the enrichment procedure were performed on a counting cell (Thoma Zeiss, Oberkochen).

Results

The percentages of nucleated erythrocytes, as counted on slides of fixed and differentially stained cells at different stages of the cell enrichment procedure, are summarized in Table I. The total cell counts at these stages are indicated in Table II. Table III shows the ratio of antibody-labeled cells of positive and negative samples after the magnetic-activated cell sorter procedure as evaluated under the fluorescent microscope; the enrichment factor of transferrin receptor–positive cells after the magnetic-activated cell sorter procedure is also indicated.

The total cell counts show that there is no substantial cell loss during the magnetic-activated cell sorter procedure itself but approximately half of the cells are lost during the immunofluorescent staining (Table II).

Before the enrichment procedure the number of nucleated erythrocytes in blood smears of fetal umbilical cord blood varied between 1% and 12% (Table I). In cytospins of positive samples of magnetic-activated cell sorter–enriched cells this percentage increased in four cases by a factor of 16, 11, 6, or 1.75; in one case the

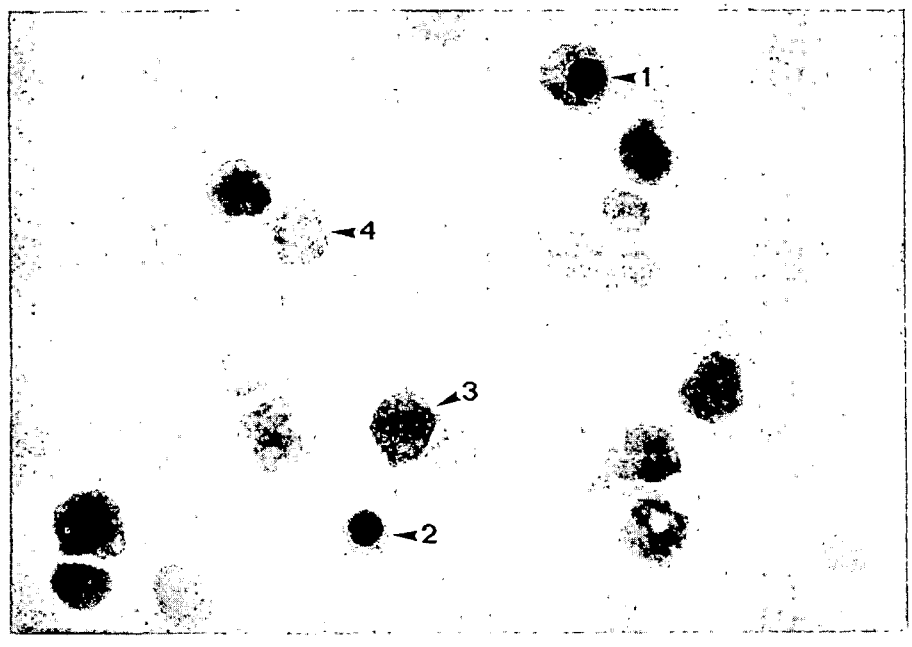

Fig. 1. Diff-Quick–stained cells labeled with anti–transferrin receptor and silver enhanced by immunogold silver staining. *1*, Labeled nucleated erythrocyte; *2*, unlabeled nucleated erythrocyte; *3*, labeled lymphocyte; *4*, labeled nonnucleated erythrocyte.

Table IV. Percentage of Leu-7–labeled cells

Sample No.	*Peripheral blood Leu-7–positive cells (%)*	*Leu-7–positive cells before MACS (%)*	*After MACS*	
			Cell count	*Leu-7–positive cells (%)*
1	47	42	1.7×10^6	96
2	27	23	0.6×10^6	95
3	5	6	2.6×10^5	65

Percentage of Leu-7–positive cells in peripheral blood before and after the magnetic-activated cell sorter *(MACS)* procedure is indicated. The number of Leu-7–positive cells was determined by FACS-SCAN analysis of immunofluorescent-stained cells. The absolute cell number before the separation was 10^7 in all three cases.

percentage of nucleated erythrocytes in cytospins was lower after the separation procedure (Table I). In this case the poor separation correlates with the higher percentage of nucleated red blood cells in the negative control after magnetic-activated cell sorting (Table I), indicating that the magnetic separation was ineffective in this case.

Fluorescence microscopy revealed that two types of morphologically different cells showed specific labeling with the fluorescein marker: (1) small cells expressing a very bright fluorescence and (2) large cells also showing a specific but weaker fluorescence. In positive samples after magnetic-activated cell sorting the proportion of fluorescein-labeled cells was always higher—varying between 1.4 and 10.8 times—than in negative controls. Yet the percentage of transferrin receptor–positive cells evaluated by fluorescence microscopy in positive and negative controls after the magnetic-activated cell sorter protocol did not correlate very well with the actual cell count of nucleated erythrocytes on corresponding cytospins (Tables I and III).

The percentage of Leu-7–positive cells before, during, and after separation with the magnetic-activated cell sorter is summarized in Table IV.

Fig. 1 shows differentially stained cells after immunogold silver labeling of an umbilical cord blood control. The ratios of transferrin receptor–positive versus transferrin receptor–negative cells as evaluated by Diff-Quick are indicated in Figs. 2 and 3. Fig. 2 shows the percentage of transferrin receptor–positive cells of each cell type after differential counts of 400 cells. Only 22% and 17% of the nucleated erythrocytes were labeled in the umbilical cord blood. In the blood of pregnant women only nonnucleated red blood cells were found.

Differential cell counts of each cell type with the corresponding percentages of specifically labeled cells are indicated in Fig. 3. In cord blood the nonnucleated

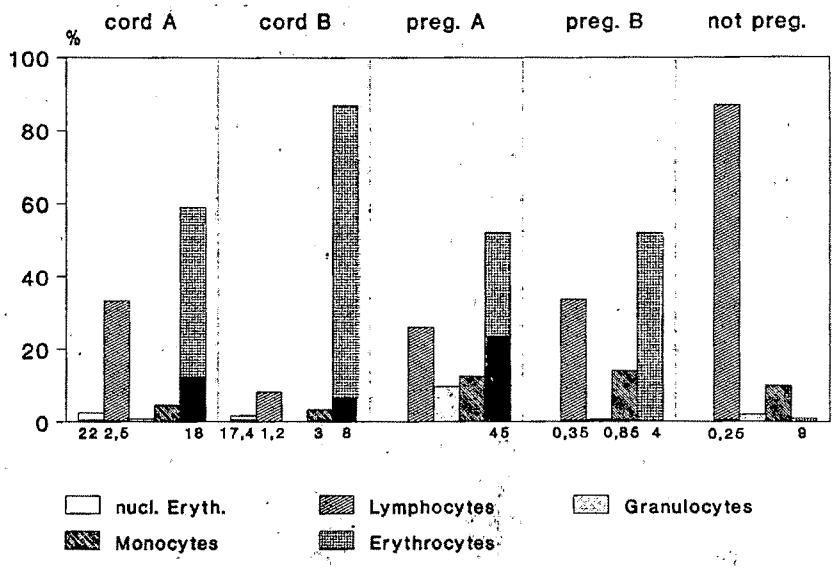

Fig. 2. Differential cell counts of transferrin receptor–labeled and immunogold silver–stained cells from two samples of umbilical cord blood and blood of two pregnant and one nonpregnant women. Proportion of different cell types in 400 cells counted. *Numbers* at bottom of graph indicate proportion of transferrin receptor–positive cells counted within each cell species.

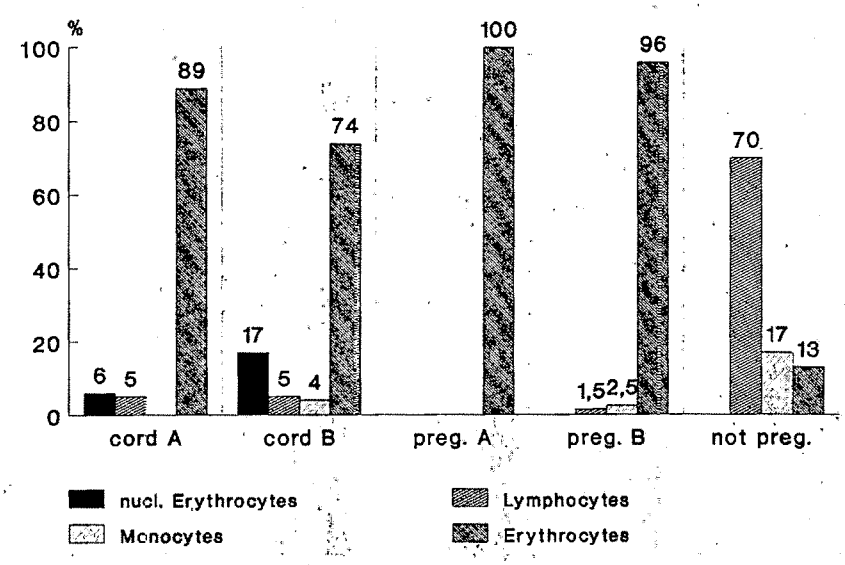

Fig. 3. Differential cell counts of transferrin receptor–labeled and immunogold silver–stained cells. Only transferrin receptor–positive cells were counted. Proportion of transferrin receptor–positive cells of each cell type is indicated at top of each *bar*.

erythrocytes are the prevalent cell type after Ficoll separation, followed by lymphocytes and few monocytes and nucleated erythrocytes; in the nonpregnant female the majority of the separated cells were lymphocytes. The ratio of monocytes, neutrophilic granulocytes, and nonnucleated erythrocytes is <10% (Fig. 3). The pregnant female controls showed somewhat intermediate cell counts after the gradient separation, with nonnucleated erythrocytes in about half of the cells, followed by lymphocytes and comparatively high counts of monocytes and neutrophilic granulocytes (Fig. 3).

Comment

There are two potential types of fetal cells to be separated to identify fetal genes in maternal circulation: trophoblast and nucleated erythrocytes. Because the results regarding the presence of trophoblast material in maternal circulation conflict[8, 11] and because the number of nucleated erythrocytes as a source of fetal de-

oxyribonucleic acid is assumed to be higher. Bianchi et al.[7] used the transferrin receptor antigen, known to be expressed on erythroblasts for enrichment. For enrichment they used the fluorescence-activated cell-sorter method.

Because this method could be too laborious and expensive for application in routine prenatal diagnosis, we evaluated the recently described and faster magnetic-activated cell sorter technique. In control separations of lymphocyte subsets we could show that the enrichment of Leu-7–positive cells was satisfactory in a shorter time period than would be necessary with the fluorescence-activated cell-sorter (Table IV). The magnetic-activated cell sorter has also proved to be well-suited for rare-event sorting.[9] Considering this efficiency of enrichment obtained with magnetic-activated cell sorter the latter can now be considered the most appropriate method in "rare event" situations such as fetal cells in maternal circulation, which probably are in the range of 10^{-6} to 10^{-7} or even lower.[1, 2, 5]

Considering the good rates of enrichment with magnetic-activated cell sorter, it should have been possible to achieve an adequate number of cells for polymerase chain reaction analysis provided there is a good marker for nucleated red blood cells.

Surprisingly, although we optimized conditions such as incubation time or temperature for labeling the nucleated fetal erythrocytes, our results indicate that the specificity and sensitivity of the transferrin receptor antibody is limited: even in umbilical cord blood only <25% of nucleated erythrocytes were transferrin receptor positive. Furthermore, the majority of labeled cells were nonnucleated erythrocytes.

These findings can also serve as an explanation for the observation of Bianchi et al.[7] that after fluorescence-activated cell sorting the number of transferrin receptor–positive cells was 300 to 4000 times higher than the number of fetal cells actually detectable by polymerase chain reaction. Although our experiments have not used the fluorescence-activated cell sorter for enrichment of transferrin receptor–positive cells, the lacking specificity of the transferrin receptor antibody would be expected to preclude an effective isolation by fluorescence-activated cell sorting.

Therefore it seems doubtful whether the use of monoclonal antibodies against transferrin receptor alone is a suitable way to enrich fetal cells in maternal circulation, even if the powerful magnetic-activated cell sorter separation technique is used.

We thank Ine Segers-Nolten for her excellent technical assistance, Angelika Dohr for cytologic evaluations, and Dr. Gioacchino Gonzales for his help with differential cell counts.

Training obstetric and family practice residents to give smoking cessation advice during prenatal care

Roger H. Secker-Walker, MB, BChir,[a, c] Laura J. Solomon, PhD,[b, c] Brian S. Flynn, ScD,[a, c, e] Sandy S. LePage, RN,[a] Jane E. Crammond, RN,[a] John K. Worden, PhD,[a, c, e] and Philip B. Mead, MD[d]

Burlington, Vermont

OBJECTIVE: Our objective was to determine the effectiveness of training obstetric and family practice residents to provide smoking cessation advice.

STUDY DESIGN: The effectiveness of the trained residents' advice was assessed from exit interviews of pregnant smokers taking part in a randomized, controlled trial of smoking cessation advice. Exit interview responses were compared by χ^2 analysis.

RESULTS: Training resulted in significant changes in the advice provided by the residents, with greater emphasis on gaining a commitment to smoking behavior change, but not in the average time providing the advice, approximately 3 minutes. Adherence to the protocol was maintained at 80%. Significantly more women who received the brief structured advice agreed to stop smoking (54%) or cut down their cigarette consumption (28%) compared with women in the control group (14% and 6%, respectively), $p = 0.0001$.

CONCLUSION: The structured advice consistently provided by the trained residents was effective in gaining commitments from pregnant smokers to change their smoking behavior. (AM J OBSTET GYNECOL 1992;166:1356-63.)

Key words: Resident training, smoking cessation advice, prenatal care, pregnancy

The risks of smoking during pregnancy are well established.[1, 2] About 25% of women smokers stop smoking when they become pregnant, and the majority of those who do not stop reduce their consumption of cigarettes by approximately 50%.[3, 4] Several studies of smoking cessation advice delivered during prenatal care have shown significant reductions in smoking in the intervention group compared with the control group,[5-9] whereas others have not.[10] These trials have tested a variety of intervention strategies, including advice from physicians,[10] advice from physicians and a specially designed leaflet,[8] individual advice and counseling,[5] extended advice from public health nurses,[9] brief advice from public health nurses and a self-help manual,[6] and self-help materials sent through the mail.[7] Three of these studies reported a significant increase in the mean birth weight of babies born to mothers in the intervention group compared with those in the control group.[5, 8, 9]

6/1/35388

Recent randomized controled trials of smoking cessation advice delivered by internists[11, 12] or by family physicians[13, 14] have shown the need to identify consistently each patient's smoking status to ensure that appropriate advice is given. The advice provided in these and other studies has included a strong recommendation to quit smoking and an attempt to gain the smoker's commitment to a quit date.[11-16]

Because advice to quit smoking delivered by physicians is cited by smokers as important in their decision to stop smoking[17] and because methods to train physicians to provide smoking cessation advice have shown some success,[13, 14, 18] we examined the effect of training residents in obstetrics and family practice to provide brief smoking cessation advice to pregnant women. This article describes the methods we used to train the residents, the smoking cessation protocol and prompt sheets they were trained to use, the evaluation of the effectiveness of the training in terms of the manner and consistency with which the smoking cessation protocol was followed, and the immediate impact on the women's agreement to change their smoking behavior.

Methods

As part of an ongoing randomized controlled trial of physician-delivered, counselor-supported smoking cessation advice during obstetric care, all obstetric ($n = 19$, 14 female and five male) and family practice ($n = 16$, 11 female and five male) residents at the University of Vermont were trained in a brief smoking cessation protocol between July 1988 and September 1990. The trial

is taking place in the Maternal-Infant Care clinic, which provides prenatal care to women with little or no insurance, 40% to 45% of whom are smokers at the onset of pregnancy. Prenatal care is provided by the obstetric and family practice residents during their rotations through the Maternal-Infant Care clinic under the supervision of a faculty member.

Pregnant women who are receiving their prenatal care through the Maternal-Infant Care clinic and who are smoking one cigarette a day or more at their first antepartum visit are randomly assigned either to the intervention group or to the basic care group. Those in the intervention group receive advice from their physician (described subsequently) and immediate referral to a smoking cessation counselor. Those in the basic care group are advised to stop smoking by their physicians and given a booklet on how to do so.

At entry into the study, the demographics, pregnancy status, and smoking histories of the women in the intervention and basic care groups were comparable, as shown in Table I. They tended to be relatively young, 55% were primigravid, most had a high school education or less, more than two thirds were not married, and 55% were receiving Medicaid. On average, they had cut down their smoking from 26 cigarettes per day before pregnancy to 14 per day at their first antepartum visit.

The intervention smoking cessation protocol. The residents are prompted to deliver the smoking cessation intervention by a protocol prompt sheet (Fig. 1) placed in the woman's chart at the first three antepartum visits and again at the fifth and thirty-sixth week visits. The key elements of the intervention delivered by the physicians are as follows: acknowledge the woman's smoking status and any progress with changing her smoking behavior since becoming pregnant, deliver a rationale for stopping smoking and a strong quit message, ask how the woman feels about quitting and acknowledge her response, ask how she could be helped and mention the availability of the smoking cessation counselor in the obstetric practice, elicit a commitment to action and a date for such action (quitting for good, quitting for 24 hours, or cutting down to half her present level of smoking), note the result on the protocol prompt sheet, and refer the woman to the smoking cessation counselor.

The smoking cessation counselor sees the woman immediately after her visit with the physician, counsels her on ways to prepare for her change in smoking behavior, and provides further contact, counseling, support, and follow-up as needed.

This protocol is repeated at the second antepartum visit for those women who are still smoking and again at the third, fifth, and thirty-sixth week visits for those women still interested in stopping smoking. Women who have quit at these visits are praised for their success, encouraged to continue nonsmoking behavior, and referred to the counselor for further support in maintaining their abstinence from cigarettes. For each of these visits the elements of protocol are included as bulleted items on the protocol prompt sheet.

The basic care smoking cessation protocol. Women randomly assigned to the control group receive the basic care advice, which is outlined on a separate protocol prompt sheet. This advice consists of acknowledging the woman's smoking status, delivering a rationale for quitting, giving a strong recommendation to quit, and providing a quit-smoking booklet at the first antepartum visit. These women are not encouraged to set a quit date, nor are they referred to the smoking cessation counselor. No prompts are provided to the residents for this group after the first visit.

Training. Before beginning training, each resident received a description of the training and copies of four

Smoking in Early Pregnancy

Name:_____ SN:_____

Smoking History: Years:_____ # Quits:_____ Longest:_____ Latest:_____

Household: # of other smokers:_____ # of adult non-smokers:_____ # of children:_____

Comments:_____

Date	Weeks	Cig/D	CO	Intent	Progress	MD/ NM	Plan and Date	Seen by Counselor

- Acknowledge smoking status, progress, and CO level. (Non-smokers typically have levels ≤ 8 ppm of CO.)
- Deliver rationale and strong quit message: "I strongly recommend that you quit smoking during your pregnancy."
- "How do you feel about quitting?" (acknowledge her response)
- "How can we help you?" (mention counselor)
- Elicit commitment to action. (quit date, 24 hr quit, cut down to half)
- Note result under "Plan and Date" and refer to counselor.

Date	Weeks	Cig/D	CO	Intent	Progress	MD/ NM	Plan and Date	Seen by Counselor

If she is still smoking

- Acknowledge smoking status, progress, and CO level.
- Deliver rationale and strong quit message.
- "How do you feel about quitting?"
- "How can we help you?"
- Elicit commitment to action. (quit date, 24 hr quit, cut down)
- Note result under "Plan and Date" and refer to counselor

If she is not smoking

- Acknowledge her quitting and give feedback on CO level.
- Praise her progress.
- Emphasize importance of staying quit throughout her pregnancy.
- Refer her to the cessation counselor for help in staying quit.

If she is still smoking

- "Have you thought about your smoking since the last time you were here?"
- "Do you want to make any changes?"
- If she wants to make a change, refer to the counselor.

If she is not smoking

- Praise her progress.
- Emphasize importance of staying quit throughout her pregnancy.
- Refer her to the cessation counselor for help in staying quit.

Date	Weeks	Cig/D	CO	Intent	Progress	MD/ NM	Plan and Date	Seen by Counselor

If she is still smoking

- Acknowledge her smoking, reinforce any progress.
- "After the child is born, smoking may have an adverse affect on its health."
- Refer to counselor if she requests assistance.

If she is not smoking

- Acknowledge and reinforce her quitting.
- Rationale and support for staying quit after pregnancy.
- "How do you feel about that?"
- "How can we help you?"
- Refer to counselor for assistance.

Fig. 1—Cont'd.

papers concerning smoking cessation advice.[5, 19-21] Each year the residents were trained by a physician and a psychologist in small groups during a 1-hour workshop. This workshop included the following: a review of the project, a description of the advice to be given to subjects in the intervention condition with a rationale for each step, the use of the specially designed protocol prompt sheet to guide this advice, a videotaped demonstration of the advice being delivered by a family physician and by an obstetrician, a role play of the advice by pairs of residents with corrective feedback, and a description of the basic care advice to be given to control group subjects. Residents who were unable to attend a workshop were trained individually.

Refresher sessions and progress. Each resident also participated in a 30-minute individual refresher session

with the psychologist a few days before starting his or her first rotation on the Maternal-Infant Care clinic. During these sessions the intervention and basic care protocols were reviewed, the intervention protocol was role-played with a simulated patient, and appropriate feedback was provided to the resident. Each month the progress of the trial and the residents' adherence to the protocols were discussed by the smoking cessation counselor during Maternal-Infant Care clinic conferences.

Evaluation of resident training. The effectiveness of the training was evaluated in three ways. First, an evaluation of the immediate impact of the training on the content and style of each resident's smoking cessation advice was conducted with the first group of residents trained in 1988. This group consisted of all 12 obstetric residents (three in each postgraduate year), and all eight first- and second-year family practice residents. This evaluation was done by comparing videotapes of the residents providing their usual advice to a simulated patient before training, with videotapes of each resident delivering the intervention protocol to the same simulated patient at the end of their refresher session.

Seven criteria, derived from the intervention protocol and selected before the videotapes were viewed, were used to rate the videotapes. These criteria were as follows: The resident provides a rationale for quitting, provides a clear, unambiguous quit message, acknowledges the woman's feelings about quitting, asks an open-ended question, elicits a commitment to a quit day, encourages the woman to select a day when she will make some change in her smoking, and indicates that the change date will be entered in the chart or that an enquiry will be made about smoking at the next visit. The tapes were scored independently by two trained raters who were blind to the training status of the resident. Scoring involved noting the presence or absence of each of the seven criteria, such that a higher score represented the inclusion of more of the desired components of the intervention protocol. Scores could range from 0 to 7. The overall interrater reliability across all seven criteria was 84%. The time the resident spent delivering the advice was also recorded.

As a second way of evaluating the training, each trained resident's adherence to the protocols was assessed from exit interviews with all the women enrolled in the trial. These exit interviews, which took place immediately after the first and second antepartum visits with their physicians and before the women in the intervention group received counseling, were conducted by a research assistant and took <2 minutes to complete. The interview included five questions about the content of the doctor's advice and two questions about what the woman agreed to do about her smoking behavior. The women's responses to the five questions about the content of the doctor's advice enabled us to see how closely the residents were adhering to the contents of the intervention and basic care protocols.

Third, the immediate effect of each resident's advice was also assessed from the exit interviews by comparing the responses of the women in the intervention and basic care groups to the two questions asking what they had agreed to do about changing their smoking behavior.

Long-term adherence to the intervention and basic care protocols was assessed by comparing the responses to the exit interviews conducted during the first year of the trial with those conducted in the second year.

Data analysis. The videotape scores and coded data from the exit interviews were entered into a personal computer. Paired Student t tests were used to compare the pretraining and posttraining videotape scores and times. χ^2 analyses of 2×2 contingency tables were used to examine the differences between the exit interview responses of the women in the intervention group compared with those in the basic care group, at the first or second antepartum visit.

This study was approved by the University of Vermont's Institutional Review Board.

Results

Comparisons of the pretraining and posttraining videotapes of the first 20 residents showed a significant effect for training on the content and style of the smoking cessation advice but not on the time taken to deliver the advice. The average score for the content and style of the advice increased from 2.15 (SD 0.88) before training to 6.05 (SD 0.69) after training, $t = -16.28$, $p = 0.0001$. The average time for delivery of the advice was 3.14 (SD 1.21) minutes before training and 3.09 (SD 0.82) minutes after training, a nonsignificant difference.

During the first 24 months of the trial, 250 women receiving their prenatal care through the Maternal-Infant Care clinic were enrolled into the trial, equally divided by random allocation between the intervention group and the basic care control group. Because this trial is still in progress and because some women have miscarried and others have transferred to private obstetric practices or have moved out of the area for their prenatal care, 103 women in the intervention group and 102 in the basic care group have been seen for their second antepartum visit. Of these, 18 women in the intervention group and three in the basic care group reported not smoking at this visit, leaving 85 smokers in the intervention group and 99 smokers in the basic care group for evaluation of advice to stop smoking or to cut down at the second antepartum visit.

The women's responses to the exit interviews after the first and second antepartum visits showed high

Table II. Exit interview responses about advice to stop smoking (number and percent of positive responses)

	First antepartum visit				*Second antepartum visit*			
	Intervention group (n = 125)		*Basic care group (n = 125)*		*Intervention group (n = 103)*		*Basic care group (n = 102)*	
Exit interview question	*No.*	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*
Did your doctor . . .								
. . . talk about smoking?	122	98	119	95	99	96	67	66*
. . . advise you to stop or stay quit?	120	96	115	92	94	91	53	52*

*$p = 0.0001$ for the 2 × 2 contingency tables comparing positive and negative responses of intervention and basic care groups for this question at this visit.

levels of adherence by the residents to both the intervention and basic care protocols. For the items, "Did your doctor talk about smoking?" and "Did your doctor advise you to stop smoking?", which address comments or advice common to both the intervention and basic care protocols, there were no significant differences at the first antepartum visit. However, at the second antepartum visit, when there were no prompts in the charts of women in the basic care group, there were substantial and highly significant differences, with fewer women in the basic care group reporting having their doctor talk about smoking or advise them to stop at this visit compared with the those in the intervention group (Table II).

For the items, "Did your doctor ask you to set a quit date?" and "Did you agree to stop?", there were highly significant differences between the two groups at both visits. Women in the intervention group were substantially more likely to report being asked to set a quit date (80%), a key part of the intervention protocol, and to agree to stop smoking (54%) at the first antepartum visit than were those in the basic care group (14% for each). Similar but less marked differences were seen at the second visit (Table III).

Responses to the three exit interview items concerning cutting down cigarette consumption also show significant differences between the two groups, with more women in the intervention group being asked to set cut down dates and agreeing to do so than those in the basic care group (Table III).

Levels of adherence to both the intervention and basic care protocols have remained remarkably steady during the course of the trial. The proportions of positive responses to the three exit interview items, "Did your doctor talk about smoking?", "Did your doctor advise you to stop smoking?", and "Did your doctor ask you to set a quit date?", did not differ significantly during the first and second years of the trial for the intervention group or for the basic care group (Table IV).

Comment

Comparison of the pretraining and posttraining videotapes clearly show that the residents changed the content and style of their advice after training but on average spent the same amount of time delivering this advice. After training the residents put substantially less emphasis on discussing the risks of smoking to the pregnancy, fetus, and mother and more emphasis on trying to gain a commitment to a smoking behavior change. Style also changed, with more of the residents asking open-ended questions after they were trained.

Adherence to the protocol by the residents has been good, as judged by the exit interviews of the women conducted immediately after their first two antepartum visits with their physicians. This level of adherence to both the intervention protocol and the basic care protocol, which has been maintained over the first 2 years of the trial, needs to be seen in the context of each obstetric resident doing one or two 2-month rotations on the prenatal service each year and each family practice resident doing a single 2-month rotation. Residents rarely see the same woman for more than two visits and may also be asked to fill in unexpectedly for their colleagues at short notice. The protocol prompt sheets that we devised for this study were modeled on those used by Solberg et al.[22] to prompt family physicians to provide smoking cessation advise[22] but also include the essential elements of the advice to be given. These prompt sheets play a key role in helping to maintain adherence to the protocol, because they show what progress the woman has made between visits and they also highlight the advice to be delivered at each visit. The prompt sheets are updated by a nurse interviewer and placed in the women's charts to cue the residents. Prompts have been used successfully by others to increase physicians' adherence to providing smoking cessation advice.[11, 13, 25, 28]

The third measure of effectiveness, gaining the woman's commitment or agreement to change her smoking behavior, also differed significantly between the inter-

There are no significant differences within groups.

vention and basic care groups. These differences, which were seen for agreeing to stop smoking and for agreeing to cut down cigarette consumption, indicate the importance of actively seeking the women's commitment to make a change in her smoking behavior before her next antepartum visit.

We recommend the inclusion of training in methods to deliver brief smoking cessation advice and, most importantly, information about office system components, such as prompt sheets, as part of every residency in obstetrics. Others have described the training of residents in family medicine and internal medicine[18, 23] and pediatrics.[23] The important elements of the brief advice to be given are well summarized in the National Cancer Institute's manual for physicians.[16] Whether physicians in established practice could be persuaded to follow a scripted protocol, such as we describe here, remains to be seen, but we think they could, because efforts by others to train family physicians and internists to follow specific elements of smoking cessation protocols have met with some success.[11-13]

The role of a nurse-counselor in the practice in supporting smoking behavior change should also be considered,[24] as there is evidence that the combination of advice from physicians and nonphysicians is more effective in promoting smoking cessation than advice from either alone.[19]

We thank William C. Wadland, MD, and Susan Smith, MD, for acting as role models in the videotapes used during the training workshops. We also thank Kathryn

Kalan (University of Massachussetts Medical School, Worcester, Massachussetts) for her invaluable advice on training residents in methods of delivering smoking cessation advice and the residents themselves for their diligence in following the protocols.

Impact of histocompatibility antigens on pregnancy outcome

Gungor Eroglu, MD,[a] George Betz, MD,[b] and Caprice Torregano, BS[a]
New Orleans, Louisiana, and Denver, Colorado

OBJECTIVE: The role of histocompatibility antigens in pregnancy outcome is controversial. This controversy may be because the initial studies were of small numbers or the patient groups were not homogeneous. The purpose of this study is to clarify these discrepant results by carrying out histocompatibility antigen typing and mixed lymphocyte culture on couples with idiopathic recurrent spontaneous abortion and by comparing results with those of fertile couples.
STUDY DESIGN: Sixty couples with at least three spontaneous abortions and 60 normal couples with at least two successful pregnancies were included. Histocompatibility antigen typing and mixed lymphocyte culture were performed by using the standard techniques. The data were analyzed statistically with the Fisher exact test and χ^2.
RESULTS: Our results failed to show any difference between normal and aborting couples with regard to HLA-A, HLA-B, and HLA-DR distribution or sharing or to mixed lymphocyte culture responsiveness.
CONCLUSION: Our study, along with other studies, emphasizes that the histocompatibility antigen system does not have an impact on pregnancy outcome. (Am J Obstet Gynecol 1992;166:1364-9.)

Key words: Recurrent spontaneous abortion, human leukocyte antigen sharing, reproductive immunology

Successful reproduction in humans continues to be an immunologic enigma as the conceptus is a semiallogenic graft with partially foreign, paternal histocompatibility antigens. There are studies[1-4] in the literature suggesting that reproductive success is due to antigenic disparity between mating partners. This disparity is necessary so that the conceptus will be immunogenic and stimulate recognition to evoke a protective mechanism against expected immunologic destruction. The role of antigenic disparity, or incompatibility, has been examined by determining sharing of histocompatibility antigens (HLA) between wife and husband. The majority of these studies were done on couples with idiopathic recurrent spontaneous abortion. Several studies reported increased sharing of HLA-A and HLA-B antigens between the partners of these couples.[5-14] Furthermore, findings of hyporesponsiveness in maternal-paternal mixed lymphocyte culture implied that compatibility in the HLA-D locus may be the cause of recurrent spontaneous abortion.[15] These findings were supported by studies showing increased HLA-DR (serodefined antigens of the D locus) sharing in such couples.[11, 16, 17] Consequently, antigenic similarity (increased HLA sharing in any of the HLA loci) between husband and wife has also been proposed as a cause of recurrent spontaneous abortion. In recent literature, however, the number of studies refuting those findings has been increasing.[18-25] Therefore the role of the HLA system in the outcome of pregnancy is controversial. These inconsistencies may be explained by studies of patients with heterogeneous causes of recurrent spontaneous abortion or because of the limited size of some groups.

The current study was undertaken to carry out HLA-A, HLA-B, and HLA-DR typing and mixed lymphocyte culture on a large and homogeneous group with recurrent spontaneous abortion. These results were compared with those of normal couples with no history of spontaneous abortion. A compilation of studies from the literature is also presented.

Material and methods

Patients. Couples with at least three spontaneous abortions and no living children in both Colorado and Louisiana were investigated thoroughly to rule out anatomic abnormalities of the uterus and genetic, endocrinologic, infectious, and autoimmune diseases. Fifty-five white couples, four black couples, and one mixed (wife white, husband black) couple met the criteria and were included in the study.

Controls. The same number of couples were matched with the aborting couples for age and race. These couples had at least two successful pregnancies and no history of spontaneous abortion.

Histocompatibility testing. HLA-A, HLA-B, and HLA-DR typing was performed with the standard National Institutes of Health technique described by Terasaki et al.[26] with tissue typing trays obtained from One Lambda (Los Angeles). Gen Trak (Plymouth Meeting,

Pa.), and Pel-Freeze (Brown Deer, Wis.). B Lymphocytes for DR typing were prepared with the nylon-wool method.[27]

Mixed lymphocyte culture. One-way mixed lymphocyte culture was performed with traditional methods. Two couples were tested at a time, one from the aborting group and one from the control group. A total of 15 different experiments were performed. Briefly, after purification of peripheral blood mononuclear cells, the samples were suspended at 1×10^6 in RPMI 1640 (GIBCO, Grand Island, N.Y.) containing 100 U/ml penicillin, 100 μg/ml streptomycin, 2 mmol/L glutamine, and 10% pooled male serum. Stimulating cells were irradiated with a dose of 2000 rads to abolish their capacity to proliferate. Cultures were carried out in triplicate in round-bottomed microtiter trays (Linbro Chemical Company, New Haven, Conn.) with 100,000 responder and 100,000 irradiated stimulator cells in a volume of 200 μl. Media and autologous and pooled lymphocytes were used to be negative and positive controls. Cultures were incubated at 37° C with 100% humidity in a 5% carbon dioxide and air atmosphere for 5 days. Tritiated thymidine, specific activity 6.7 Ci/mmol (New England Nuclear, Boston) was then added, 1 μCi per well. After 12 hours of additional incubation, plates were harvested in a multiple harvester. The samples were then placed in vials containing scintillation fluid and the amount of radioactivity that was incorporated into the deoxyribonucleic acid of proliferating cells was determined by liquid scintillation counting.

The results of mixed lymphocyte culture were expressed as relative response and were calculated by

$$\text{Relative response} = \frac{\text{Test counts/min} - \text{Autologous counts/min}}{\text{Median response counts/min} - \text{Autologous counts/min}} \times 100$$

When the relative response ≥20, mixed lymphocyte culture was accepted to be positive in another way, stimulation occurred.

Statistical analysis. The data were analyzed with the Fisher exact test and χ^2 analysis.

Results

HLA class I and II antigens (HLA-A, HLA-B and HLA-DR). The distribution of HLA-A, HLA-B, and HLA-DR antigens was analyzed in both aborting and normal couples. The frequency of antigens is shown in Tables I and II. There was no significant difference between the two groups. Also, no association between recurrent spontaneous abortion and a particular HLA

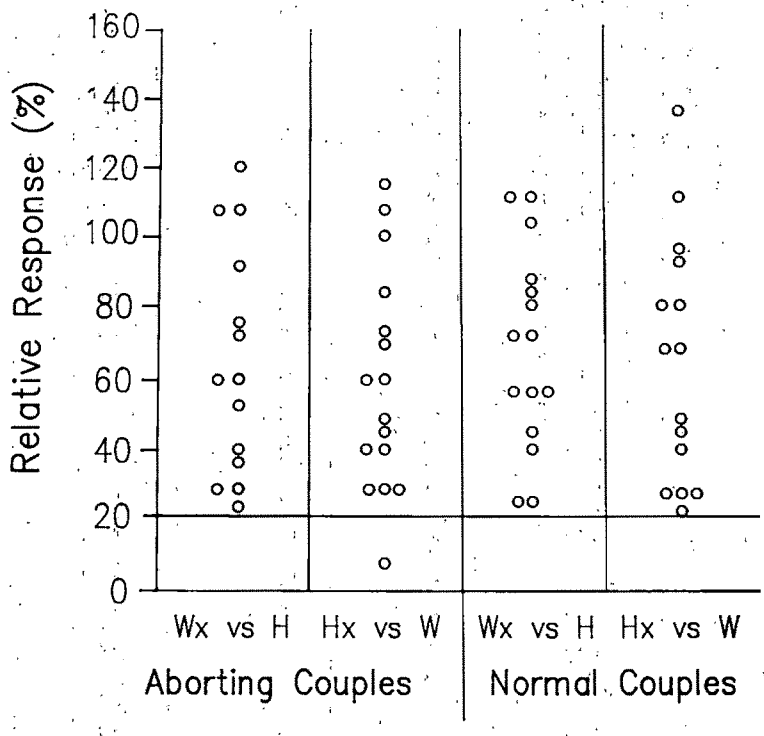

Fig. 1. Mixed lymphocyte culture in 15 aborting and 15 normal couples. Reactivity was expressed as relative response. Positive response was accepted when relative response ≥20. Wife *(Wx)* versus husband *(H);* wife's irradiated cells as stimulator, husband's cells as responder; husband *(Hx)* versus wife *(W);* husband's irradiated cells as stimulator, wife's cells as responder.

antigen was found. Furthermore, no excess of maternal or paternal homozygosity was observed.

The number of shared HLA antigens in both groups is shown in Table III. To accentuate the distinction between aborting and normal couples, the data were analyzed separately for each locus and for all the loci together. As illustrated, the results for each locus were not different from those found with normal couples. In a combined analysis of HLA-A, HLA-B and HLA-DR, 30% (18/60) aborting couples did not share any antigen, 40% (24/60) shared one antigen, 25% (15/60) two antigens, and only 5% (3/60) had three antigens

*Found an association between DQ locus and primary recurrent spontaneous abortion.

†Analysis of results was done differently in this study.

in common. Those percentages in normal couples were, respectively, 20%, 55%, 20%, and 3.33%.

The HLA sharing data from this study and from other published data are presented in Table IV. For the purposes of classification, the results are divided into group A, those studies that reported increased HLA sharing in aborting couples, and group B, those that did not. As can be seen, the number of studies reporting increased HLA sharing (group A) is slightly more than those who did not, but the number of cases in group B is more than those studies of group A.

Mixed lymphocyte culture—stimulation indices. The results of one-way mixed lymphocyte culture are shown in Fig. 1. All cultures showed normal stimulation except for that of couple 12, which showed a low level of stimulation when the wife's cell was responder to the husband's cells and to third party cells. Female lymphocytes from couples with recurrent spontaneous abortion stimulated and responded equally to cells both from their husbands' cells and third parties' cells (husbands of control groups). Similarly, cells from husbands of couples with recurrent spontaneous abortion were able to stimulate and respond to cells from their wives and the control group. When the relative response of couples with recurrent spontaneous abortion was compared with normal couples, there was no difference between the two groups.

Comment

The data presented here failed to show an increased incidence of antigen sharing between the partners of couples with recurrent spontaneous abortion when compared with controls. Furthermore, the distribution of HLA, HLA-A, HLA-B, or HLA-DR antigens in couples with recurrent spontaneous abortion was very similar to that of control group.

Increased sharing of HLA-A and HLA-B antigens in couples with recurrent spontaneous abortion was first reported by Komlos et al.[5] in 1977 (Table IV); similar findings were reported by other groups.[8-14] Other reports suggested that sharing of class II antigens (HLA-D) was even more significant than sharing in class I (HLA-A, HLA-B, HLA-C) antigens.[11, 16, 17] These findings of increased HLA sharing have been interpreted both genetically and immunologically to explain the etiology of idiopathic recurrent spontaneous abortion. The immunologic interpretation suggests that an immune response is necessary for proper im-

plantation and maintenance of pregnancy. The genetic interpretation postulates that the gene associated with fetal wastage is a recessive lethal gene linked to an HLA locus and that linkage disequilibrium exists between these loci.[13] It appears, however, from our results that increased HLA sharing has no relation to recurrent spontaneous abortion. Twenty-three percent of our normal couples shared two to three antigens without any history of spontaneous abortion. Obert et al.[28] reported an association between increased HLA sharing and idiopathic recurrent spontaneous abortion in Hutterites,* who have increased inbreeding. The authors also, however, reported that sharing HLA antigens does not preclude normal pregnancy. In agreement with our findings, the association between recurrent spontaneous abortion and increased HLA sharing was not found by other investigators.[18-25] This contradiction may involve a number of variables, including the increased number of split HLA antigens (subgroups of core antigens, i.e., HLA-A10 was split to be HLA-A25 and A26, etc.), sample size, and lack of homogeneity of the population studied. We hoped to eliminate these variables in this report by using a relatively large homogeneous group. Furthermore, we used split antigens, not core antigens.

Mixed lymphocyte culture is one of the methods to investigate allograft reactions in vitro and has been used by some investigators in an attempt to detect feto-maternal immunologic interactions. In contrast to previous reports of depressed mixed lymphocyte culture responses[8-11, 15, 20] between wives and husbands of aborting couples, our studies failed to demonstrate a depression of mixed lymphocyte responsiveness in such couples. When results were compared with normal couples, the relative response did not deviate from that of the control group. Thus our findings are in agreement with Thomas et al.[15]

Although our study has resulted in negative findings, we are in agreement with recent literature emphasizing that the status of the HLA system does not have a major impact on pregnancy outcome or that traditional typing and mixed lymphocyte culture are not the right criteria to sufficiently define the role of incompatibility in human reproductive performance.

We thank Dr. Jawahar Tiwari for his excellent statistical analysis.

Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy

Donald M. Peebles, MB, BS, A. David Edwards, MB, John S. Wyatt, MB, Anthony P. Bishop, Mark Cope, PhD, David T. Delpy, DSc, and E. Osmund R. Reynolds, MD

London, England

OBJECTIVE: The purpose of this study was to measure by near-infrared spectroscopy changes in human fetal cerebral oxyhemoglobin, deoxyhemoglobin, and cerebral blood volume during labor and to calculate mean cerebral hemoglobin oxygen saturation.
STUDY DESIGN: The effects of uterine contractions with and without fetal heart rate decelerations were compared in eight singleton term fetuses. Results were analyzed by analysis of variance.
RESULTS: In six of eight fetuses normal uterine contractions were associated with proportional decreases in both oxyhemoglobin and deoxyhemoglobin and a fall in cerebral blood volume without desaturation of cerebral hemoglobin. Contractions with fetal heart rate decelerations produced different results in that oxyhemoglobin fell but deoxyhemoglobin rose, indicating cerebral desaturation. In two of the eight fetuses normal contractions were associated with increases in oxyhemoglobin, deoxyhemoglobin, and cerebral blood volume; no decelerations were seen in either fetus. Mean cerebral hemoglobin oxygen saturation calculated during normal contractions was 43% ± 10% (SD).
CONCLUSION: Uterine contractions were associated with detectable changes from baseline in cerebral oxyhemoglobin, deoxyhemoglobin, and cerebral blood volume. (Am J Obstet Gynecol 1992;166:1369-73.)

Key words: Near-infrared spectroscopy, fetal brain oxygenation, labor, uterine contraction, fetal heart rate deceleration

No current techniques allow the direct assessment of fetal cerebral oxygenation during labor, although information can be obtained about the oxygenation and acid-base status of the fetal scalp.[1-4] Because of the relative transparency of biologic tissue to light in the near-infrared region of the spectrum (700 to 1000 nm), it is possible to transmit near-infrared light through ≤8 cm of tissue to obtain spectroscopic information noninvasively from the brain. The technique of near-infrared spectroscopy has been used to provide quanti-

tative data on cerebral oxygenation and hemodynamics in the newborn infant.[5-7] We adapted this technique to measure changes in fetal cerebral hemoglobin concentration, oxygenation, and blood volume during labor. The purpose of our study was to examine the effects of uterine contractions with and without fetal heart rate decelerations on these variables and to measure fetal mean cerebral hemoglobin oxygen saturation.

Material and methods

We studied eight singleton term fetuses of gestational age 39 to 42 (median 40) weeks and birth weight of 2.6 to 4.2 (median 3.6) kg during labor, the details of which are given in Table I. Observations were recorded continuously for a period of 169 to 343 (median 208) minutes until 360 to 0 (median 140) minutes before delivery occurred. Near-infrared spectroscopy was continued in two fetuses throughout the second stage until delivery. In seven fetuses the postnatal course was uncomplicated, but one infant required a short admission to the neonatal unit for observation because of acidemia at birth. The project was approved by the University College London Faculty of Clinical Sciences Committee on the Ethics of Clinical Investigation, and written maternal consent was obtained.

The technique of near-infrared spectroscopy depends on absorption by the chromophores oxyhemoglobin and deoxyhemoglobin of near-infrared light transmitted through the fetal head. The modified Beer-Lambert law describing optic absorption in a highly scattering medium may be expressed as OD = acLB + G, where OD is the tissue attenuation (optical densities), a is the absorption coefficient of the chromophore (millimoles per liter per centimeter), c the concentration of chromophore (millimoles per liter), L the distance between the points where light enters and leaves the tissue (centimeters), B a path-length factor that takes account of the scattering of light in the tissue (which causes the optic path-length to be greater than L), and G a factor related to the geometry of the tissue. If during a study L, B, and G remain constant, changes in chromophore concentration can be calculated from the change in absorption divided by the product of aLB.[8] The absorption coefficients of oxyhemoglobin and deoxyhemoglobin are known,[9] and a mean value for B of 4.39 (SD 0.28) has been obtained.[10]

Fiberoptic bundles that conveyed light to and from the fetal head were introduced through the cervix after it had dilated to 3 to 6 (median 4) cm after rupture of the amniotic membranes. The ends of the bundles were held 3 cm apart in a specially designed silicone rubber molding (Fig. 1) placed against the side of the fetal head during routine vaginal examination. Coupling between the fiber ends and the fetal scalp was maintained

by maternal tissue pressure. No significant difficulty in placement was encountered, and no maternal discomfort was apparent. All the babies were examined after delivery, and no skin marking caused by the molding was found. The fiber bundles conveyed near-infrared light to a spectrophotometer (NIR 500 or 1000, Hamamatsu Photonics KK, Hamamatsu City, Japan) that detected changes in attenuation at three or six different wavelengths (NIR 500 or 1000, respectively) between 775 and 908 nm. These were converted into concentration changes of oxyhemoglobin and deoxyhemoglobin with a previously established algorithm.[9,10] Changes in total cerebral hemoglobin concentration were obtained as the sum of changes in oxyhemoglobin and deoxyhemoglobin, and changes in cerebral blood volume were calculated from cord hemoglobin concentration and changes in total cerebral hemoglobin concentration, assuming a cerebral/large-vessel hematocrit ratio of 0.69.[7] Fetal heart rate (FHR) and uterine activity were monitored continuously with a cardiotocograph (Hewlett Packard 80300A, Hewlett Packard, Andover, Mass.). All data were recorded simultaneously onto magnetic disk for subsequent analysis.

Results

Data were obtained without difficulty from all eight fetuses. Observations were available during 82 contractions, of which 20 were associated with FHR decelerations (a fall in FHR of ≥15/min for ≥15 seconds).

During normal contractions (n = 44) in six of the eight fetuses, oxyhemoglobin and deoxyhemoglobin fell from the baseline, the mean fall being 0.50 ± SD 0.27 μmol/100 gm brain tissue and 0.78 ± 0.60 μmol/100 gm, respectively (Figs. 2, *a*, and 3). Total hemoglobin concentration fell by 1.15 ± 0.60 μmol/100 gm and cerebral blood volume by 0.70 ± 0.39 ml/100 gm. The changes in cerebral hemoglobin concentrations occurred simultaneously with contractions. Twenty early FHR decelerations were observed in five of these six fetuses. As with normal contractions, the FHR decelerations were associated with a fall in oxyhemoglobin of 0.87 ± 0.54 μmol/100 gm; in contrast, deoxyhemoglobin always rose (Figs. 2, *b*, and 3) by 1.1 ± 0.60 μmol/100 gm ($p < 0.01$ vs change in deoxyhemoglobin in normal contractions, analysis of variance), indicating transient cerebral desaturation.

In the remaining two fetuses a different pattern was observed during normal contractions (n = 18), with a consistent rise in both oxyhemoglobin and deoxyhemoglobin of 0.71 ± 0.43 μmol/100 gm and 1.22 ± 0.55 μmol/100 gm, respectively. Total hemoglobin concentration rose by 1.86 ± 0.95 μmol/100 gm and cerebral blood volume by 0.97 ± 0.52 ml/100 gm. No decelerations were observed in these two fetuses.

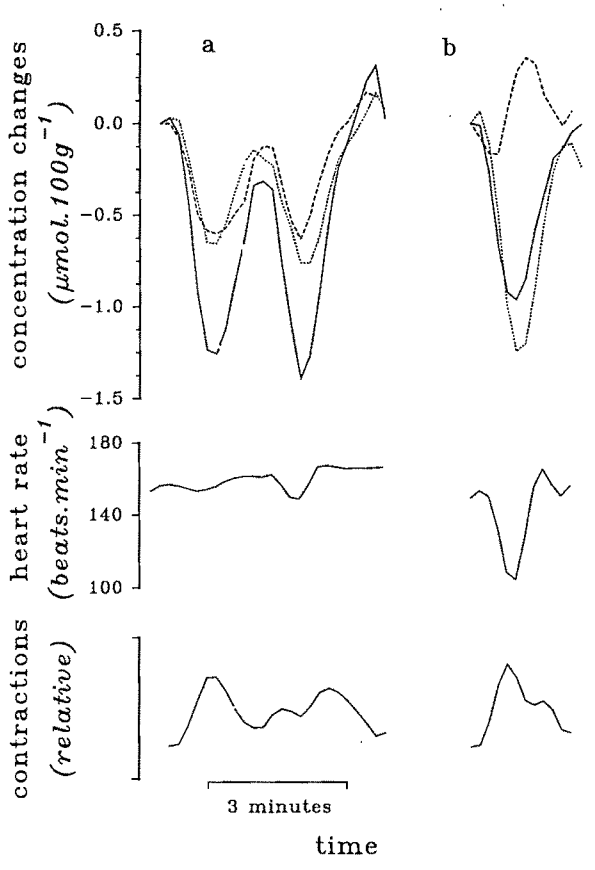

Fig. 2. Changes from an arbitrary baseline in the cerebral concentrations of oxyhemoglobin *(dotted line)*, deoxyhemoglobin *(dashed line)*, and total hemoglobin *(solid line)* in the same fetus during two normal contractions **(a)** and a contraction with an early FHR deceleration **(b)**.

In seven fetuses mean cerebral hemoglobin oxygen saturation was calculated during 14 normal contractions (range 1 to 3 per fetus, median 2) where oxyhemoglobin and deoxyhemoglobin changed in parallel. With the formula Mean cerebral hemoglobin oxygen saturation percent = 100 × Change in concentration of oxyhemoglobin/Change in concentration of oxyhemoglobin + deoxyhemoglobin, an estimate for mean cerebral hemoglobin oxygen saturation of 43% ± 10% (SD) was obtained. In one of the two fetuses in whom observations were continued until delivery, mean cerebral hemoglobin oxygen saturation remained in the range of 50% to 64%, the cord arterial oxygen tension was 2.0 kPa, and the pH_a 7.31. In the other, however, mean cerebral hemoglobin oxygen saturation fell from 35% ± 2% to 1% ± 3% (Fig. 4); in this infant the cord arterial oxygen tension was 1.2 kPa and pH_a 7.17.

Comment

These data describe the effects of uterine contractions with and without fetal heart rate decelerations on

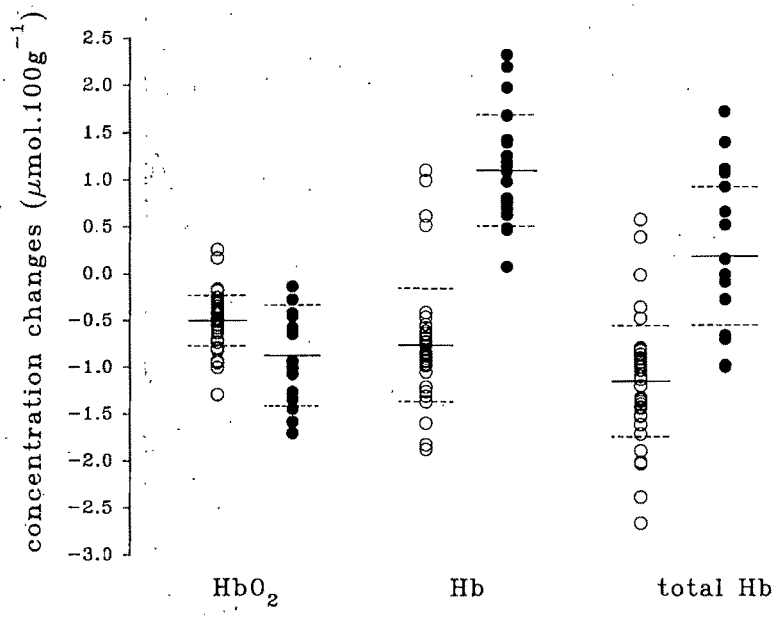

Fig. 3. Data from six fetuses showing maximum changes in cerebral oxyhemoglobin, deoxyhemoglobin, and total cerebral hemoglobin concentration during normal uterine contractions *(open circle)*, and those with FHR decelerations *(solid circle)*. Mean values ± SD are indicated.

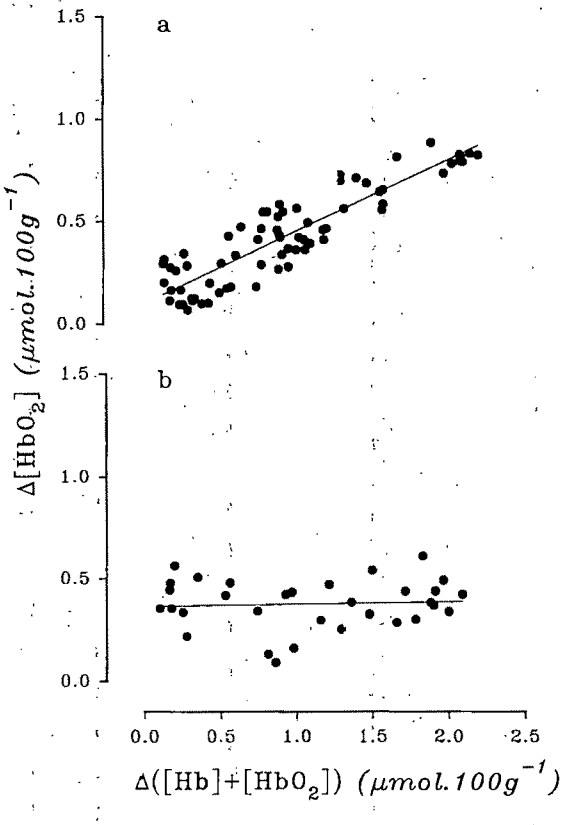

Fig. 4. Change in oxyhemoglobin and change in oxyhemoglobin plus deoxyhemoglobin during the first and second stages of labor in one fetus. Each point represents a 10-second collection of data during three consecutive contractions 165 to 141 minutes **(a)** and 23 to 18 minutes **(b)** before delivery. Mean cerebral hemoglobin oxygen saturation calculated from the least-mean-squares regression was 35% ± 2% **(a)** and 1% ± 3% **(b)**.

human fetal cerebral hemoglobin concentration, blood volume, and oxygenation. Comparison with other reports is difficult because there are no previous data from human studies and no animal experiment has measured similar hemodynamic variables. However, the fall in cerebral blood flow[11] and cerebral oxygen consumption[12] associated with head compression in fetal sheep suggests that the change in total hemoglobin concentration observed during normal uterine contractions probably reflected a balance between direct pressure effects, reducing cerebral blood flow and obstruction of venous drainage. The usual change in cerebral blood volume observed with normal contractions implied a fall in total cerebral blood volume of 30%, assuming neonatal values for cerebral blood volume.[7] Fetal heart rate decelerations were uniformly associated with transient cerebral desaturation, which was presumably caused by a reduction in cerebral oxygen delivery. Although we cannot rule out an effect on our results of a small change in the optical path-length during contractions, any such change could not have caused the large alterations in variables reported here. In the future continuous measurement of path-length will be possible.[13]

Our study reports the first measurements of fetal mean cerebral hemoglobin oxygen saturation. The measurements were made during contraction-related changes in total cerebral hemoglobin concentration when oxyhemoglobin and deoxyhemoglobin rose or fell in constant proportion, indicating that global saturation remained unchanged during the contraction. As such the measurement represented an average of

oxygen saturation throughout the brain. The relation between mean cerebral hemoglobin oxygen saturation and arterial or venous oxygen saturation is thus not necessarily linear; changes in the volume of a vascular compartment will affect the average saturation. However, changes in compartmentalization of blood during a measurement would cause the relation between oxyhemoglobin and deoxyhemoglobin to be nonlinear and this can be detected by near-infrared spectroscopy. Also, significant falls in cerebral oxygen delivery will be observed (as in our study) because the fall in global saturation is bigger than any possible effect of a change in compartment size.

The need for a method to assess fetal brain oxygenation has been previously emphasized.[14] At present the degree of hypoxemia to which a fetus is exposed during labor can be assessed by measuring acid-base status from intermittent scalp blood samples[2] or retrospectively from the umbilical cord blood, or by attempting to measure the pH,[3] oxygen tension,[4] or saturation[1] of the fetal scalp blood. The technique of near-infrared spectroscopy has several features that recommend it for intrapartum monitoring of the fetus. It is the first technique to allow continuous bedside monitoring of changes in human fetal cerebral hemoglobin concentration and oxygenation during labor. As an optic method it does not require electric coupling with the skin. Unlike scalp pulse oximetry, near-infrared spectroscopy directly interrogates the brain and is not dependent on the presence of an arterial pulsation. Near-infrared spectroscopy should supplement the present methods available for diagnosing fetal compromise in labor, such as FHR monitoring and scalp blood pH studies, and finally lead to a better understanding of the pathophysiologic characteristics of intrapartum cerebral hypoxemia.

We thank P. Hurley and the obstetric consultants and labor ward staff at University College Hospital for their help.

Risk factors for small-for-gestational-age birth in a preterm population

Janet M. Lang, PhD, ScD,[a] Amy Cohen, AB,[b] and Ellice Lieberman, MD, DrPH[b, c]
Boston, Massachusetts

OBJECTIVE: The objective of this study was to discover any distinct risk factors for small-for-gestational-age birth among premature infants.
STUDY DESIGN: Demographic and obstetric risk factors were compared for 136 small-for-gestational-age prematures and 636 appropriate-for-gestational-age premature infants.
RESULTS: Three significant risk factors for growth retardation among premature infants were found: black maternal race (odds ratio 2.2; 95% confidence interval (1.4 to 3.5); maternal toxemia (odds ratio 3.2; 95% confidence interval 1.7 to 6.1); and either low maternal weight gain (odds ratio 4.0; 95% confidence interval 1.8 to 8.8) or missing information on maternal weight gain, which could be a marker for late or no prenatal care (odds ratio 4.9; 95% confidence interval 1.9 to 12.6). Maternal smoking rates were similar in the small- and appropriate-for-gestational-age groups (42% and 43%, respectively).
CONCLUSIONS: Toxemia, weight gain, and race are likely risk factors for small-for-gestational-age birth in both preterm and term populations; within the already high-risk domain of prematurity, maternal smoking did not appear to confer added risk for small-for-gestational-age birth. (Am J Obstet Gynecol 1992;166:1374-8.)

Key words: Infant, small-for-gestational-age; infant, premature; infant, low-birth-weight

The incidence of intrauterine growth retardation has been estimated at 20% to 41% among preterm infants (infants born before 37 weeks' gestation).[1-3] Premature small-for-gestational-age (SGA) infants, when compared with appropriate-for-gestational-age (AGA) infants of similar gestational age, have been found to more frequently have low Apgar scores and to be more likely to require resuscitation at birth.[3] Additionally, such SGA preterm infants have been noted to be at increased risk for apnea, seizures, and neonatal death.[3] Heinonen et al.[3] have noted that the neonatal course of such infants is more likely to be complicated. In a population-based study in Finland they found that among preterm SGA infants 98% (48 of 49) had complications of some type during the neonatal period as compared with 78% (53 of 68) AGA premature infants.

Although risk factors for the occurrence of term SGA have been examined in the literature,[4, 5] risks for preterm SGA birth have been less frequently investigated. Hack and Fanaroff,[1] in a study of 182 very-low-birth-weight infants admitted to a neonatal intensive care unit (35 SGA and 147 AGA), noted that pregnancy-related hypertension was positively associated with SGA birth. Heinonen et al.[3] in a study of 117 preterm infants (49 SGA, 68 AGA) noted that the occurrence of preterm SGA was associated with maternal essential hypertension and toxemia.

In this paper we evaluate potential risk factors associated with the occurrence of preterm SGA birth among very-low-birth-weight infants and note how these risk factors compare with established risks for term SGA birth.

Methods

To recruit subjects for the National Collaborative Study of Patent Ductus Arteriosus, 3490 very-low-birth-weight babies were monitored at 13 clinical centers. All monitored babies weighed between 500 and 1750 gm at birth and had an expected viability of at least a few hours. Demographic information and details regarding the course of pregnancy and delivery were obtained from medical records and maternal postpartum interviews. Further details regarding data collection for this collaborative study have been reported elsewhere.[6]

Gestational age was determined by physical examination of the infant, according to the method of Dubowitz et al.[7] The gestational age for this study population was restricted to 30 and 31 weeks as a consequence of the weight criteria for inclusion in the collaborative study (500 to 1750 gm). For some gesta-

tional ages, excluded babies <500 gm would more likely be SGA than AGA; for other gestational ages, excluded babies >1750 gm would more likely be AGA than SGA. To minimize this differential exclusion of SGA or AGA babies, we restricted the study to those gestational ages where few babies were excluded from the study base either because of low (<500 gm) or higher (>1750 gm) birth weights. We defined those gestational ages as ones where birth weight distributions became near normal and assessed this criterion by the comparability of the median and mean birth weights. For the gestational ages of 30 and 31 weeks, the median sex-specific birth weight exceeded the mean sex-specific birth weight by only 9 to 34 gm.

Babies were categorized as SGA if their birth weight was <10th percentile of gender-specific weights given by Williams et al.[8] All other babies were categorized as AGA. For 30 weeks' gestation the 10th percentile values for males and females were 1007 and 902 gm, respectively; for 31 weeks' gestation the values were 1159 and 1041 gm.

Rates of SGA were calculated for each gestational age group. Crude comparisons between the SGA and AGA groups were then made along a number of maternal demographic and medical variables.

Adjusting only for infant gender and gestational age, the effect of race was evaluated by means of a logistic model. Effects of other maternal demographic characteristics and variables describing the pregnancy and delivery were then examined by adding each variable in turn to the logistic model that already included variables for gestational age, gender, and race. Finally, a more fully adjusted model was constructed in which a number of potential risk factors were simultaneously included in the model. For all the logistic regressions, the effects are summarized by odds ratios and 95% confidence intervals.

Results

Data were evaluated from 772 singleton, premature, very-low-birth-weight babies, 136 SGA babies, and 636 AGA babies. The overall rate of SGA in this premature population was 17.6%. This rate was similar across the two gestational age categories (17.1% at 30 weeks' gestation and 18.2% at 31 weeks, Table I). Although the mean birth weight varied by gestational age, the mean difference between SGA and AGA birth weights was relatively uniform across the two gestational age categories, with SGA infants weighing about 400 gm less than AGA infants.

Other characteristics of the SGA and AGA groups are given in Table II. SGA and AGA babies differed in race and a number of other maternal characteristics, with the largest crude differences being in education, prepregnancy weight, weight gain, multivitamin and iron supplementation use, toxemia or other hypertension, and type of labor (spontaneous or not). There were only small differences between the SGA and AGA babies in maternal age and maternal smoking during this pregnancy. The individual and combined effects of these factors were evaluated with a series of logistic regressions. Seven factors were significantly related to the risk of preterm SGA birth in simple models that adjusted for only gestational age, gender and race: toxemia, other hypertension, maternal weight gain, prepregnancy weight, multivitamin and iron supplementation use, maternal employment, and type of labor. However, only race, toxemia, and gaining ≤5 pounds during the pregnancy or having no information about weight gain available remained significantly associated with preterm SGA in the more fully adjusted model (Table III).

Mean SGA − mean AGA	−409	−402	−403

Comment

Low birth weight can result from either a short gestation (preterm birth), growth retardation (SGA birth), or both. We have previously argued that these separate routes to low birth weight must be studied separately to discover any distinct risk factors.[5, 9]

In this study we have focused on SGA birth among premature infants, comparing the prenatal experiences of preterm SGA babies with those of preterm AGA babies. We compared the two groups in the largest study to date along 23 demographic, medical, and obstetric factors (Table II). Although there were a number of crude differences between the groups, after adjusting for the joint effects of all of these factors, the risk of SGA among preterm births increased independently with only three factors: black maternal

race (odds ratio 2.2, 95% confidence interval 1.4 to 3.5), the incidence of maternal toxemia during the pregnancy (3.2, 1.7 to 6.12), and maternal weight gain, specifically the categories of ≤5 pounds during the pregnancy (4.0, 1.8 to 8.8) and no available information about maternal weight gain (4.9, 1.9 to 12.6). Previous studies have reported similar crude associations in preterm infants.[1, 3] For example, Hack and Fanaroff[1] reported rates of pregnancy-related hypertension of 26% for SGA mothers and 8% for AGA mothers; Heinonen et al.[3] reported rates of toxemia and hypertension of 41% for SGA mothers and 7% for AGA mothers. These numbers are similar to the rates found in this study, 26% toxemia or hypertension for SGA mothers versus 11% for AGA mothers. However, neither previous study reported results from multivariate models adjusting for a range of potential confounding factors.

The risk factors we found for SGA birth among prematures (toxemia, maternal weight gain, and race) are also risk factors for SGA birth among term babies.[4, 10] Growth retardation as a consequence of toxemia has been frequently reported.[4, 10] The role of low maternal weight gain is more problematic; low maternal weight gain may be a cause of growth retardation or another factor may influence both growth retardation along with factors related to weight gain. We interpret the high risk of SGA associated with missing information about weight gain to suggest that this unavailability is a likely marker for poor or late prenatal care, situations where weight gain information would not be routinely available. As for the role of race, although it consistently predicts adverse birth outcomes,[4, 11, 12] it may not do so in a strictly causal fashion. Black race may be a marker for a residual cluster of "bad experiences," social, economic, behavioral, and medical, that cause SGA.

Cigarette smoking during the pregnancy has been found to be a major risk factor for term SGA birth.[4, 12, 13] We did not find it to be a risk factor for SGA birth among premature infants. Other studies of SGA among preterm infants either reported no information about smoking[1] or reported only that their numbers were too small to evaluate its effect.[3] In our study 328 women reported smoking during pregnancy. However,

*Estimates are adjusted simultaneously for gestational age and gender, plus all of the variables listed in this table.

the proportions were quite similar in the SGA and AGA groups (42% and 43%, respectively).

Although ours is the largest study to date of risk factors for SGA birth within a preterm population, the study is not without its limitations. Because the data from 30% of the women in our study did not contain information about their last menstrual period, (LMP), we estimated the gestational age of infants from Dubowitz infant scores[7] rather than from the LMP. Spinnato et al.[14] have shown that Dubowitz ages are systematic overestimates of (clinically corroborated) LMP derived ages, especially for infants <33 weeks' gestation. However, this careful comparative study found no evidence that Dubowitz ages were differentially inaccurate for SGA versus AGA babies. Thus the consequence of using gestational age estimates derived from Dubowitz scores rather than (clinically corroborated) LMP reports is that the percent of SGA may be overestimated because the use of a cut-off value for a higher Dubowitz gestational age (rather than the lower LMP gestational age) may misclassify as SGA some babies who are really AGA. The effect of this nondifferential misclassification would be to dilute the observed results in the direction of the null. Therefore positive results that emerge in spite of this potential bias (such as the effects of black maternal race, maternal toxemia, and maternal weight gain) may be underestimates of the true effects of those variables. However, for null results (such as the effect of maternal cigarette smoking) the interpretation is more complicated. The observed null result could reflect a true null result, or it could result from the dilution (due to nondifferential misclassification) of a small-to-moderate-sized effect. Neither option can be conclusively excluded on the basis of this study alone.

The effect of maternal smoking on risk of SGA birth among premature infants remains an open question, although the combination of positive and null results from this study suggests that within the already high-risk domain of premature infants, maternal smoking may not confer any added risk for SGA status. However, for maternal toxemia, weight gain, and race, all three are risk factors for prematurity among AGAs, for SGA among term babies,[4, 10, 12] and, as suggested by the present study, risk factors for SGA among premature infants.

Treatment of unruptured tubal pregnancy by laparoscopic instillation of hyperosmolar glucose solution

Peter F. Lang, MD, Karl Tamussino, MD, Werner Hönigl, MD, and George Ralph, MD

Graz, Austria

Sixty patients with unruptured tubal pregnancy were treated with local laparoscopic instillation of 50% glucose solution. This treatment was successful in 49 (98%) of 50 patients with an initial serum human chorionic gonadotropin level of ≤2500 mU/ml and in six (60%) of 10 with an initial level >2500 mU/ml. No side effects were seen. The average hospital stay of patients who did not require a second intervention was 5.2 days (range 3 to 10). The average time between glucose instillation and the decline of serum human chorionic gonadotropin levels below the level of detectability was 21.3 (±14.3) and 30.2 (±10.9) days in patients with serum levels ≤2500 mIU/ml and >2500 mIU/ml, respectively. Five patients (8%) underwent a second laparoscopy (n = 4) or laparotomy (n = 1) because of stable or increasing human chorionic gonadotropin levels and progressing clinical symptoms. We conclude that laparoscopic instillation of hyperosmolar glucose solution is safe, technically simple, and effective in the treatment of unruptured tubal pregnancies associated with a serum human chorionic gonadotropin level ≤2500 mIU/ml. (Am J Obstet Gynecol 1992;166:1378-81.)

Key words: Tubal pregnancy, laparoscopy, conservative treatment

A variety of medical, laparoscopic, and surgical techniques have been developed to preserve the affected tube in those patients with a tubal pregnancy wanting to preserve fertility.[1, 2] Medical efforts in this direction led to the use of methotrexate, which is effective against tumors of the trophoblast.[3] A similar effect was

achieved by prostaglandins.[4] However, both prostaglandins and methotrexate can cause systemic side effects.[5, 6]

Laparoscopic local application of hyperosmolar glucose causes local necrobiosis, and we have used it for the treatment of unruptured tubal pregnancies. A prospective, randomized study showed hyperosmolar glucose to be as effective as prostaglandins in this setting.[7] The current report presents our experience with 60 consecutive patients treated with laparoscopic local instillation of 50% glucose solution into an unruptured tubal pregnancy.

Patients and methods

A total of 127 unruptured tubal pregnancies were treated at our hospital in the 22-month period between February 1, 1989, and December 1, 1990. A diagnosis of tubal pregnancy was made on the basis of history, clinical and pelvic examination, levels of human chorionic gonadotropin (hCG) in the urine and serum, and vaginal ultrasonographic studies. All diagnoses were confirmed by laparoscopy. A total of 77 patients received local medical treatment; 60 of these patients were treated with hyperosmolar glucose solution and are the subject of this report. The remaining 17 patients were treated with prostaglandins according to the protocol of an earlier study.[7] Preoperative criteria for an attempt at treatment with glucose were written: informed consent, desire for preservation of fertility, and stable circulation with no signs of hemorrhagic shock. Intraoperative inclusion criteria were complete visualization of the small pelvis, an intact serosal covering of the tube, ≤200 ml of hematoperitoneum, and no active bleeding.

After inspection of the pelvic organs, any blood present was suctioned out of the abdomen. The affected tube was grasped with atraumatic forceps introduced through a second, suprasymphyseal incision. Five to 20 milliliters of a 50% glucose solution was injected into the pregnancy through a 15-gauge needle 40 cm long introduced through the second suprasymphyseal incision. Injection was stopped when there was notable swelling of the tube or when glucose solution was seen escaping from the fimbrial end of the tube. Any residual fluid was suctioned out of the pouch of Douglas.

Pulse, blood pressure, and red blood cell counts were monitored for the first 48 hours. hCG levels in the urine and serum were measured at least once preoperatively and daily during the hospital stay. The overall correlation between hCG levels in the urine and the serum was 0.8 ($p < 0.0001$, Spearman's rank correlation test). The patients were discharged from the hospital when hCG levels declined for 2 subsequent days. Urinary hCG levels were measured every 2 to 3 days until they declined below 50 mIU/ml, the lower limit of detection (Test Pack HCG urine, Organon Teknika, Boxtel, Netherlands). Thereafter, hCG levels were measured in the serum (hCG MAIA clone immunoradiometric assay, magnetic solid phase; Serono Diagnostics, Norwell, Mass.) at 1-week intervals until the lower limit of detection (5 mIU/ml) was reached. All patients were offered hysterosalpingography 3 months or more after the procedure.

Table I. Clinical data according to initial serum hCG concentration of 60 patients undergoing laparoscopic instillation of hyperosmolar glucose solution into unruptured tubal pregnancy (mean ± SD)

	Initial serum hCG	
	≤2500 mIU/ml	*>2500 mIU/ml*
Age (yr)	26.8 ± 4.8	27.4 ± 5.0
Gestational age (days)	49.4 ± 8.3	47.2 ± 7.3
Urinary hCG (mIU/ml)	811 ± 758	4100 ± 2644
Serum hCG (mIU/ml)	582 ± 533	4348 ± 2007
Size of pregnancy (cm)	3.0 × 1.5	3.3 × 1.8
Hemoperitoneum (ml)	20 ± 31	22 ± 29
Localization (right)	56	40
Primigravid women (%)	34	50

Results

The clinical data of the patients are shown in Table I. Fifty-seven of the tubal pregnancies were located in the ampullary or isthmoampullary portion of the tube; three were located in the tubal isthmus. The average hospital stay of the 55 patients who did not require a second operation was 5.2 days (range 3 to 10). The patients were separated into two groups on the basis of preoperative serum hCG levels of ≤2500 mIU/ml ($n = 50$) and >2500 mIU/ml ($n = 10$). There were no differences in the results according to the amount of glucose injected.

Tubal pregnancies with initial serum hCG ≤2500 mIU/ml. The courses of serum hCG levels in these 50 patients are shown in Fig. 1. Glucose instillation was successful in 49 (98%) patients. The average time between glucose instillation and the decline of serum hCG below the level of detectability was 21.3 (± 14.3) days. One patient with an initial serum hCG level of 1200 mIU/ml undewent a second laparoscopy 28 days after the first procedure because of a renewed increase of hCG levels and lower abdominal pain. The pregnancy had not yet ruptured but was larger than at primary surgery; the affected tube was removed endoscopically at the patient's request.

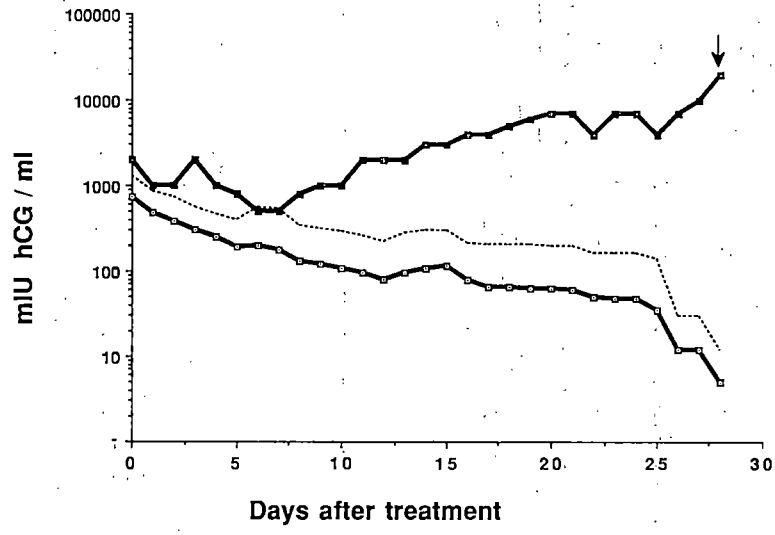

Fig. 1. Mean course of hCG excretion in 50 patients with initial serum hCG level ≤2500 mIU/ml (*dashed line,* SD). *Lower solid line* represents course of 49 patients treated successfully and *upper solid line* shows course of patient who required reintervention *(arrow).*

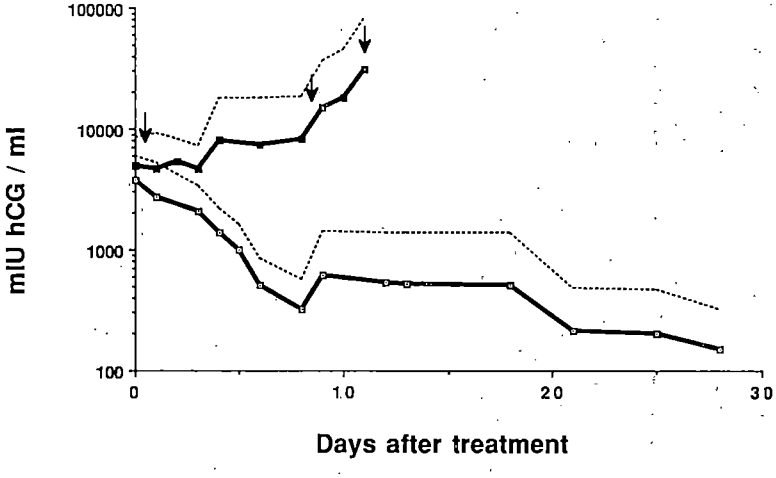

Fig. 2. Mean course of hCG excretion in 10 patients with initial serum hCG level >2500 mIU/ml (*dashed lines,* SD). *Upper solid line* indicates course in three patients who required reintervention *(arrows). Lower solid line* indicates course in six patients treated successfully. Patient who underwent laparotomy for ruptured tubal pregnancy on day 32 did not undergo follow-up examinations.

Tubal pregnancies with initial serum hCG >2500 mIU/ml. The courses of the serum hCG levels in these 10 patients are shown in Fig. 2. Local glucose instillation was successful in six (60%) patients. The average time between glucose instillation and the decline of serum hCG below the level of detectability was 30.2 (± 10.9) days. Four patients underwent a second operation at 1, 9, 11, and 32 days, respectively. One of these patients had an isthmic tubal pregnancy. Three patients underwent a second laparoscopy with salpingectomy (n = 2) or salpingotomy (n = 1). One patient did not come to follow-up examinations and underwent laparotomy for a ruptured tubal pregnancy at another hospital 32 days after glucose instillation.

Follow-up. Twenty-two patients underwent hysterosalpingography 3 to 6 months after glucose instillation. Patency and normal configuration of the affected tube were seen in 18 patients; four patients showed occlusion of the affected tube. Twelve patients achieved an intrauterine pregnancy. Two of these patients probably became pregnant through the affected tube because hysterosalpingography had shown occlusion of the contralateral tube. Two patients developed a renewed tubal pregnancy (one in the contralateral and one in the same tube).

Comment

Highly sensitive and specific hCG assays and vaginal ultrasonography have made possible the early diagnosis and treatment of tubal pregnancies before rupture.[8, 9]

The higher the hCG level, the greater the mass of viable trophoblastic tissue and the greater the risk of rupture.[10] Pansky et al.[11] have recently reviewed nonsurgical modalities for the management of tubal pregnancy.

Local application of methotrexate or prostaglandins has been successful in about 80% to 90% of unruptured tubal pregnancies.[12-14] However, both substances can cause systemic side effects, and the application of methotrexate in the immediate vicinity of the ovary seems at least questionable. Hyperosmolar glucose causes local dehydration and necrobiosis of the trophoblastic tissue and thus resolution of the tubal pregnancy. A second laparoscopy of isolated patients has shown no signs of damage to the tubal wall. None of the patients in the current series had side effects attributable to glucose instillation.

The average time required for serum hCG levels to decline below the level of detectability (21.3 ± 14.3 days in patients with an initial level of ≤2500 mIU/ml) is of concern insofar as the patients must be followed during this period. The decline in hCG levels is obviously more precipitous after interventions such as salpingotomy or salpingectomy that remove the trophoblast. However, in a study comparing glucose instillation with prostaglandin treatment there were no differences in the resolution time of hCG levels.[7] In a series of 12 patients treated by transvaginal intratubal methotrexate administration, Tulandi et al.[15] reported a resolution time of 14 to 120 days from injection to undetectable hCG levels. However, the initial serum hCG levels in these patients ranged from 1593 to 21,000 mIU/ml. The mean resolution time in a series of 14 patients with initial hCG levels of 78 to 8000 mIU/ml given only expectant treatment was 20.3 ± 13.1 days.[16] Overall, it is difficult to compare the hCG resolution times among different studies because of different inclusion criteria, particularly initial hCG levels.

The long average hospital stay of the successfully treated patients in this series (5.2 days) was mainly due to the design of the research protocol. Also, the health care system in Austria reimburses hospitals for the number of days a patient is in the hospital and patients thus tend to be hospitalized longer than necessary. We now discharge clinically stable patients on the day after surgery if the hCG is not rising and follow them on an outpatient basis.

The tubal mucosa is not a favorable site for nidation, and tubal pregnancies can heal spontaneously.[11] In the largest study of initial expectant management, Fernandez et al.[16] found nine (64%) of 14 ampullary tubal pregnancies to resolve spontaneously. Seven of these nine patients had initial hCG levels ≤1000 mIU/ml, as did 43 patients in our series. However, at present it is difficult to distinguish between pregnancies that will resolve spontaneously and those that will rupture the tube.[11]

The results of this series suggest that local instillation of hyperosmolar glucose is safe, effective and free of side effects in the treatment of unruptured tubal gestations with a serum hCG level ≤2500 mIU/ml. The technique is simple and the integrity of the tubal wall is preserved. Glucose instillation does not seem indicated for ectopic gestations associated with a serum hCG level >2500 mIU/ml.

The relationship between acute inflammatory lesions of the preterm placenta and amniotic fluid microbiology

Roberto Romero, MD, Carolyn M. Salafia, MD, Apostolos P. Athanassiadis, MD, Shuichi Hanaoka, MD, Moshe Mazor, MD, Waldo Sepulveda, MD, and Michael B. Bracken, PhD

New Haven and Danbury, Connecticut, and Detroit, Michigan

OBJECTIVE: Our objective was to determine the relationship between microbial invasion of the amniotic cavity and the presence and severity of acute inflammatory lesions in the placenta.

STUDY DESIGN: Placental histologic and amniotic fluid microbiologic studies were performed in 92 consecutive patients who were admitted with preterm labor and intact membranes and delivered within 48 hours after amniocentesis.

RESULTS: The prevalence of a positive amniotic fluid culture was 38% (35 of 92). There was a strong association between the presence and severity of inflammation in the amnion, chorion-decidua, umbilical cord, and chorionic plate and the results of the amniotic fluid culture ($p < 0.0001$ for each tissue section). Three patterns of inflammation of the chorion-decidua were identified: marginating, nonmarginating, and a mixed pattern. The marginating and the mixed patterns of inflammation were strongly associated with the presence of a positive amniotic fluid culture. Acute inflammation of the chorionic plate was the most sensitive indicator of a microbial invasion of the amniotic cavity (sensitivity 96.6%), and funisitis and umbilical vasculitis had the highest specificity (85.7%).

CONCLUSION: The presence of acute inflammatory lesions of the chorioamniotic membranes can serve as a marker of microbial invasion of the amniotic cavity. (Am J Obstet Gynecol 1992;166:1382-8.)

Key words: Chorioamnionitis, intraamniotic infection, placenta, preterm labor, prematurity, parturition, inflammation

Acute inflammation of the chorioamniotic membranes is one of the most common histopathologic lesions of the placenta. Traditionally, histologic chorioamnionitis has been considered an indicator of amniotic fluid infection.[1-8] However, there is a paucity of scientific evidence to support this view. Previous studies have demonstrated an association between acute inflammatory lesions of the placenta and the recovery of microorganisms from the subchorionic plate[9,10] and the chorioamniotic space.[11] However, recovery of microorganisms from these extraamniotic sites cannot be used as proof of an amniotic fluid infection. It seems logical that the evidence supporting a relationship between histologic chorioamnionitis and amniotic fluid infection can only be derived from a comparison of pathologic placental examination and amniotic fluid microbiologic studies. Only one study has examined the relationship between amniotic fluid microbiologic features and placental pathology; this study used transcervical collection of amniotic fluid for microbiologic studies and therefore is limited in its ability to discriminate between specimen contamination and the true microbiologic state of the amniotic cavity.[12] Another limitation of this study is that patients had their membranes ruptured, which could lead to intrapartum microbial invasion of the amniotic cavity and cloud interpretation of the data.

The purpose of this study was to determine the relationship between the presence, severity, distribution, and pattern of acute inflammatory lesions of the placenta and microbiologic findings of the amniotic fluid. To study this issue we have used a unique data set: microbiologic studies of amniotic fluid and placentas obtained from women with preterm labor and intact membranes who were delivered within 48 hours of amniocentesis.

Material and methods

The placental histologic types and amniotic fluid microbiologic features were examined in consecutive patients admitted to Yale–New Haven Hospital who met

Table I. Grading system for acute intrauterine inflammations

Amnion and chorion-decidua
Grade 1: One focus of at least five polymorphonuclear leukocytes
Grade 2: More than one focus of grade 1 inflammation or at least one focus of 5 to 20 polymorphonuclear leukocytes
Grade 3: Multiple or confluent foci of grade 2
Grade 4: Diffuse and dense acute inflammation
Umbilical cord
Grade 1: Polymorphonuclear leukocytes within inner third of umbilical vein wall
Grade 2: Polymorphonuclear leukocytes within inner third of at least two umbilical vessel walls
Grade 3: Polymorphonuclear leukocytes in perivascular Wharton jelly
Grade 4: Panvasculitis and funisitis extending deep into Wharton jelly
Chorionic plate
Grade 1: One focus of at least five polymorphonuclear leukocytes in subchorionic fibrin
Grade 2: Multiple foci of grade 1 in subchorionic fibrin
Grade 3: Few polymorphonuclear leukocytes in connective tissue or chorionic plate
Grade 4: Numerous polymorphonuclear leukocytes in chorionic plate and chorionic vasculitis

Modified from Salafia et al.[14]

these criteria: (1) preterm labor with intact membranes (gestational ages 22 to 36 weeks) and (2) preterm delivery within 48 hours after amniocentesis. Data from some of these patients have been reported in other studies by our group; data from placental histologic examination have not been previously reported. The standard of care at our institution is to offer amniocentesis for microbiologic assessment of the amniotic cavity to all women admitted with the diagnosis of preterm labor with intact membranes. Patients gave written informed consent for amniocentesis. Additionally, some patients gave permission to withdraw additional fluid for research purposes. Women with preterm premature rupture of membranes were excluded from this study because microbial invasion of the amniotic cavity in the context of rupture of membranes may be a fundamentally different pathologic process to that occurring in preterm labor with intact membranes.

After amniocentesis, amniotic fluid was transported immediately to the laboratory in a capped plastic syringe. These conditions precluded air contact with the specimen. Plating occurred within 30 minutes after collection in most cases. Microbiologic studies included amniotic fluid cultures for aerobic and anaerobic bacteria and *Mycoplasma hominis* and *Ureaplasma urealyticum*, by methods previously described in detail.[13] Placental microbiologic studies, including cultures of the subchorionic fibrin and chorioamniotic space, were not performed. This is not the standard of practice in our institution. The relationship between cultures from these sites and placental histologic type has been addressed by other authors.[9-11]

Gross and microscopic studies of the placentas were performed according to an established protocol previously described by Salafia et al.[14] This protocol has been used for the study of the prevalence and distribution of acute placental inflammatory lesions in uncomplicated term pregnancies.[14] Briefly, tissue samples included sections of umbilical cord, the chorionic plate (taken from an area with minimal subchorionic fibrin), and a roll of membranes extending from the area of membrane rupture to the placental margin. All blocks of tissue were fixed with 10% buffered formalin and embedded in paraffin. Sections of tissue blocks were stained with hematoxylin and eosin and read by a perinatal pathologist (C.M.S.) who was blinded to the clinical information. The presence of acute inflammation of the extraplacental membranes, cord, and chorionic plate was noted and graded with a semiquantitative scale (Table I). Any tissue that contained cells identified as polymorphonuclear leukocytes was graded as positive for acute inflammation.

The pattern of inflammation in the chorion-decidua was classified as marginating, nonmarginating, or mixed, a combination of both. The marginating pattern consisted of the presence of neutrophils piled up along the interface between the amnion and chorion-decidua (Fig. 1). A nonmarginating pattern was defined as any other distribution of neutrophils in the chorion-decidua. Frequently this pattern appears as a destructive decidual inflammatory process (necrotizing type of inflammation) (Fig. 2).[14]

Contingency tables were generated with each type of histologic section (umbilical cord, chorionic plate, amnion, chorion, and pattern of inflammation) and amniotic fluid culture results. A χ^2 for trend was used to analyze contingency tables, which included ordered data. The data were analyzed with the True Epistat statistical package (Epistat Services, Richardson, Tex.). A replication study was conducted for the various tissue sections, and the intraclass correlation coefficients and the 95% confidence intervals were calculated for each one.[15] Histologic slides from 20 patients were read by

Fig. 1. Acute marginating chorioamnionitis-deciduitis, grade 3 *(thin arrow)*, and amnionitis, grade 2 *(thick arrow)*. (Hematoxylin and eosin. Original magnification × 10.)

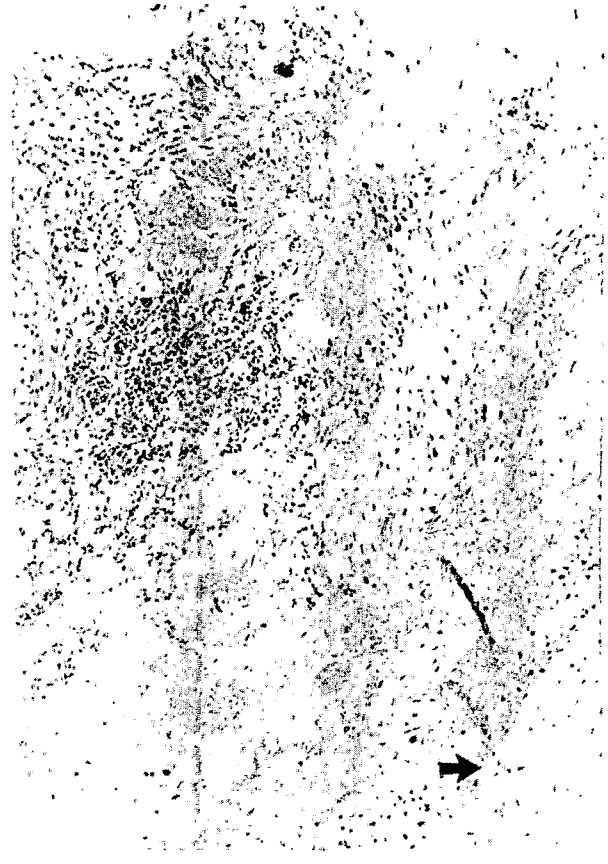

Fig. 2. Acute nonmarginating (necrotizing) deciduitis, grade 1, with maternal neutrophils focally present in decidua (*arrow* at junction of cellular and connective tissue chorion). (Hematoxylin and eosin. Original magnification × 10.)

a pathologist (C.M.S.) on 10 different occasions. The observer was kept blinded from clinical information and previous readings.

Results

This study included 92 patients who met the entry criteria. Positive amniotic fluid cultures were detected in 38% (35 of 92) of the patients. Table II illustrates the amniotic fluid microbial isolates from women in this study. No correlation could be demonstrated between the inoculum size and the severity of inflammation in any histopathologic sections. Table III illustrates the distribution of acute inflammatory lesions in the membranes, chorionic plate, and umbilical cord according to the result of the amniotic fluid culture. In each instance the more severe the inflammatory process, the more likely it was that the patient had a positive amniotic fluid culture.

There was a correlation between the grade of inflammation in the amnion and that of the chorion-decidua ($r = 0.46$; $p = 0.00004$, Spearman rank test). A similar correlation was found between the grade of inflammation of the umbilical cord and in the chorion-decidua ($r = 0.30$; $p = 0.01$, Spearman rank test). We also found a strong correlation between the presence or absence of inflammation in the chorionic plate and inflammation in other tissue sections ($p < 0.01$). However, it was not possible to demonstrate a correlation between the grade of inflammation in the chorionic plate and that observed in any other tissue sections ($p > 0.05$).

Table IVA displays the frequency and distribution of the pattern of inflammation in the chorioamniotic membranes according to the results of the amniotic fluid culture. Table IVB displays the results of multiple comparisons with partition χ^2. The presence of any inflammation (nonmarginating, marginating, or mixed) was significantly associated with a positive amniotic fluid culture. Furthermore, inflammation with a marginating pattern (alone or with a mixed pattern) was also associated with a positive amniotic fluid culture when compared with a nonmarginating pattern alone. Additionally, inflammation in the chorion-decidua of the mixed type was significantly associated with a

positive amniotic fluid culture compared with a nonmarginating or marginating pattern alone. Finally, inflammation in the marginating pattern alone was significantly associated with a positive culture when compared with inflammation in only the nonmarginating pattern.

Table V shows the conventional statistics used to describe a screening test, which placental examination could be with respect to microbial invasion of the amniotic cavity. In spite of being based on a relatively small number, the high sensitivity of the chorionic plate and the high specificity of the umbilical cord are clearly evident and worth noting. The positive predictive value indicates that about 66% of those defined as being infected would actually be so, but 96.6% (negative predictive value) of those defined as not being infected would truly not be, given the same prevalence of disease found in our study population.

A replication reliability study was conducted on the amnion, chorion-decidua, chorionic plate, and umbilical cord. The intraclass correlation coefficients and the one-sided 95% confidence intervals are presented in Table VI. The values indicate excellent agreement for readings from umbilical cord and amnion. The agreements for the chorionic plate and chorion-decidua were also very good.

Table II. Microbial isolates from patients with positive amniotic fluid cultures

Microorganisms	*Incidence*
Mixed infection*	7
Fusobacterium sp.	6
Gardnerella vaginalis	6
Mycoplasma hominis	5
Ureaplasma urealyticum	4
Peptostreptococcus	3
Bacteroides sp.	3
Lactobacillus sp.	2
Streptococcus viridans	1
Streptococcus agalactiae	1
Haemophilus influenzae	1
Veillonella parvula	1
Staphylococcus aureus	1
Capnocytophaga	1

*More than three microorganisms isolated from a patient.

Comment

The results of this study clearly demonstrate a strong association between the presence, severity, and distribution of acute inflammatory lesions in the placenta and the recovery of microorganisms from the amniotic fluid. These findings support the traditional view that there is a relationship between the presence of acute inflammatory lesions of the placenta and membranes and intraamniotic infection. A similar relationship has been documented in the context of term gestation with a different method for amniotic fluid microbiologic studies (transcervical aspiration).[12]

The prevalence of positive amniotic fluid cultures in this study was 38%, which is higher than the 21.6% that we previously reported in a large prospective study.[16] The apparent discrepancy is most likely related to one of the enrollment criterion of this study: delivery within 48 hours of amniocentesis. This criterion was chosen to restrict the time interval between amniocentesis and delivery, so that the microbiologic status of the amniotic cavity and histologic examination of the placenta could be compared in a temporally meaningful way. In previous studies we have documented that women with positive amniotic fluid cultures have a shorter interval between amniocentesis and delivery than women with negative cultures.[16]

We examined the frequency and degree of acute inflammatory lesions in several tissue sections, including the umbilical cord, chorionic plate, amnion, and chorion-decidua. These tissue sections afford the possibility of examining both fetal and maternal responses to the presence of an intraamniotic infection. Although funisitis, umbilical vasculitis, and chorionic vasculitis are fetal responses,[17, 18] neutrophil infiltration of the chorionic plate, amnion, chorion, and decidua are essentially the consequence of a maternal response to infection.[18]

Our data showed a correlation between the presence and degree of inflammation in the amnion and chorion-decidua tissue sections. Because neutrophils in the avascular amnion and chorion-decidua are of maternal origin and these tissues are immediately adjacent to each other, it is not surprising to find a high degree of correlation between the severity of inflammation in these tissue sections. Similar observations have been reported in studies of placentas of women at term.[12]

In spite of the strong association between the presence or absence of inflammation in the chorionic plate and inflammation in other tissues sections, we could not demonstrate a correlation between the grade of inflammation in the chorionic plate and that observed in any other tissue sections. The degree of inflammation in the chorionic plate was often more severe than the one observed in other tissue sections. The higher sensitivity of the chorionic plate in the detection of a positive amniotic fluid culture can be attributed to the greater blood flow and availability of neutrophils in the intervillous space (in direct proximity to the chorionic plate) than that in the decidua capsularis.

Although inflammation of the umbilical cord was the least sensitive indicator of a positive amniotic fluid culture, it had the highest positive predictive value. The lower sensitivity is easily explained if one takes into account the physical distance between the chemotactic

Table III. Presence and severity of inflammation in different tissue sections according to amniotic fluid culture results

Tissue	Culture	Grade of inflammation					χ^{2*}	df	p

stimuli of bacteria in the amniotic fluid and the fetal white blood cells contained within the vessels of the umbilical cord. Temporally, umbilical vasculitis and funisitis are probably late events in the course of an intraamniotic infection. Therefore these inflammatory lesions would be expected to have a high positive predictive value for the detection of intraamniotic infection. This expectation was met by our data. Our observations are consistent with those of Maudsley et al.,[19] who demonstrated that the more advanced the inflammation in the umbilical cord section, the more likely that other tissue sections had inflammation.

A new observation made in this study is that a marginating pattern of inflammation in the chorion-decidua was strongly associated with a positive amniotic fluid culture. The distribution of neutrophils suggests that the source of chemotactic stimuli is located in the amniotic fluid. In contrast, the distribution of neutrophils in the nonmarginating necrotizing inflammatory lesion suggests that the location of the chemotactic stimuli is in the decidua.

The pathways of ascending intrauterine infection have not been clearly elucidated. One possibility is that microorganisms from the vagina and cervix transverse the membranes adjacent to the cervix and colonize the amniotic fluid. Alternatively, microorganisms may ascend to broadly colonize the chorioamniotic membranes and decidua and only at a later stage gain access to the amniotic fluid.

We propose that these two pathways of infection should lead to different histologic patterns of inflammation. In the first pathway, a predominant marginating pattern of inflammation would be found, because the chemotactic stimuli would be generated in the amniotic cavity. This tenet is consistent with the results of this study in which a marginating pattern was signifi-

Table V. Diagnostic indices of different tissue sections for the identification of a positive amniotic fluid culture*

	Sensitivity	*Specificity*	*Positive predictive value*	*Negative predictive value*
Amnion	82.3 (0.65, 0.93)	78.4 (0.64, 0.88)	71.1 (0.55, 0.85)	86.9 (0.73, 0.95)
Chorion-decidua	87.0 (0.70, 0.96)	57.6 (0.43, 0.71)	55.1 (0.40, 0.69)	88.2 (0.75, 0.96)
Chorionic plate	96.6 (0.82, 0.99)	65.9 (0.50, 0.79)	65.9 (0.50, 0.79)	96.6 (0.82, 0.99)
Umbilical cord	74.2 (0.56, 0.87)	85.7 (0.72, 0.94)	78.7 (0.61, 0.91)	82.3 (0.69, 0.91)
Pattern	77.4 (0.58, 0.90)	71.4 (0.56, 0.83)	63.1 (0.46, 0.78)	83.3 (0.68, 0.93)

95% Confidence limits are shown in parentheses.

*Diagnostic indices were calculated with the following criteria for the definition of acute inflammation in various tissue sections: amnion, grades 1 through 4; chorion-decidua, grades 2 through 4; umbilical cord, grades 1 through 4; chorionic plate, grades 2 through 4.

cantly associated with the presence of positive amniotic fluid culture. In the second pathway, microbial invasion of the decidua would lead to a nonmarginating necrotizing pattern. We believe that this type of inflammatory lesion results from the appearance of neutrophils in the decidua where the foci of bacteria are located. Necrotic lesions would be the consequence of local tissue destruction by the microorganisms. If this pathway is used, the infection would be restricted mainly to the decidua and chorion, and the prevalence of positive amniotic fluid cultures should be low. Our data support this interpretation. Indeed, the prevalence of positive amniotic fluid cultures was similar in patients without inflammatory lesions of the placenta and in patients with a nonmarginating pattern. Finally, if microorganisms that initially cause an extraamniotic infection (chorionitis-deciduitis) invade the amniotic cavity or if microorganisms traverse intact membranes and colonize the decidua, a mixed pattern of inflammation would be observed. Under these circumstances, the chemotactic stimuli reside in both the decidua and amniotic cavity.

A major finding in this study is that acute inflammatory lesions of the placenta can be present in the absence of positive amniotic fluid cultures for microorganisms. Several explanations can be invoked: (1) The infection is located extraamniotically; (2) the inoculum size required to elicit an inflammatory response may be smaller than that which is required for isolation of microorganisms by standard microbiologic techniques; (3) nonviable microorganisms may release chemotactic factors (i.e., endotoxin) that elicit inflammation but would not yield a positive amniotic fluid culture; (4) inflammation may be caused by microorganisms that escape detection by the microbiologic techniques used in this study; (5) infection may not be the only cause of acute inflammatory lesions; (6) an intraamniotic infection may have developed in the interval between amniocentesis and delivery.

In conclusion, the results of the present study support the view that in the setting of preterm labor with intact membranes, the majority of inflammatory lesions of the chorioamniotic membranes are associated with microbial invasion of the amniotic cavity in the absence of overt clinical signs of infection. Placental pathologic examination provides a noninvasive means of assessing the likelihood of microbial invasion of the amniotic cavity.

Table VI. Intraclass correlation coefficient and one-sided 95% confidence intervals for the various tissue sections

Tissue	*Correlation coefficient*	*One-sided 95% confidence interval*
Amnion	0.9317	0.8917
Chorion-decidua	0.8335	0.7479
Chorionic plate	0.8869	0.8251
Umbilical cord	0.9686	0.9494
Pattern	0.7090	0.5830

Maternal serum α-fetoprotein, β-human chorionic gonadotropin, and unconjugated estriol levels in midtrimester trisomy 18 pregnancies

Frank Greenberg, MD,[a] Deborah Schmidt, RN,[a] Asha T. Darnule, MD, PhD,[b] Barbara R. Weyland, MPH,[a] Esmie Rose, PhD,[a] and Elliot Alpert, MD[b]

Houston, Texas

OBJECTIVE: The purpose was to evaluate the levels of maternal serum human chorionic gonadotropin, α-fetoprotein, and unconjugated estriol in trisomy 18 pregnancies compared with normal singleton pregnancies.

STUDY DESIGN: Sera from 14 trisomy 18 pregnancies (13 retrospectively and one prospectively ascertained) were analyzed for human chorionic gonadotropin, α-fetoprotein, and unconjugated estriol.

RESULTS: The α-fetoprotein levels in the 10 trisomy 18 pregnancies without open neural tube or ventral wall defect had a median of 0.65 multiple of the median, although two had α-fetoprotein levels above 2.5 multiples of the median. The human chorionic gonadotropin levels had a median of 0.32 multiple of the median and the unconjugated estriol levels had a median of 0.56 multiple of the median. Although most women with trisomy 18 pregnancies had serum human chorionic gonadotropin levels that were <1.0 multiple of the median, three had markedly elevated human chorionic gonadotropin levels (>5.0 multiples of the median).

CONCLUSION: Our data are partially consistent with those previously published but suggest the possibility of a bimodal distribution of α-fetoprotein and human chorionic gonadotropin levels in trisomy 18–affected pregnancies, unrelated to a neural tube or abdominal wall defect. The efficiency of screening for trisomy 18 prospectively, using the three serum markers, requires further evaluation. (AM J OBSTET GYNECOL 1992;166:1388-92.)

An association between low levels of maternal serum α-fetoprotein (AFP) and both fetal trisomy 21 and trisomy 18 was noted by Merkatz et al.[1] An association between low maternal serum levels of unconjugated estriol in midtrimester and fetal trisomy 21 was found by Canick et al.[2] Bogart et al.[3, 4] also discovered an association of elevated maternal serum β-human chori-

onic gonadotropin (β-hCG) levels with fetal trisomy 21 but low β-hCG levels with fetal trisomy 18. The use of the three serum markers has been suggested as a means of prenatal screening for fetal trisomy 21, inasmuch as the levels of the three markers and maternal age can be used to calculate an estimated risk of trisomy 21.[5]

Canick et al. recently reported data on the levels of β-hCG, unconjugated estriol, and α-fetoprotein in pregnancies with trisomy 18.[6] In 10 pregnancies with trisomy 18, they found low AFP levels in association with very low levels of β-hCG (median 0.27 multiple of the median, range 0.13 to 1.07) and very low levels of unconjugated estriol (median 0.49 multiple of the median, range <0.15 to 0.72). We analyzed serum β-hCG, AFP, and unconjugated estriol levels in 14 trisomy 18 pregnancies (13 retrospectively and 1 prospectively) from our Prenatal Screening Program and compared it with serum from normal, singleton control pregnancies.

Material and methods

Specimens. The Baylor Maternal Serum α-Fetoprotein Screening Program, a medical school–based, not-for-profit prenatal screening program was established in 1981. Women screened by the program come mainly from the Houston area, but are also from other areas of Texas and western Louisiana and include women from both private obstetric practices and public health clinics. The use of low maternal serum AFP levels to screen for increased risk of fetal Down syndrome began in 1985, and over 50,000 women have been screened. Prospective screening using AFP, β-hCG, and unconjugated estriol was initiated in January 1990. Of these, 13 singleton trisomy 18 pregnancies have been ascertained since 1985. Five had low maternal serum AFP levels (Down syndrome risk at delivery ≥1:360) and four had elevated maternal serum AFP levels (>2.5 multiples of the median). These nine women were offered amniocentesis and were confirmed to have trisomy 18 prenatally. In the remaining four pregnancies the women had "normal" maternal serum AFP levels but were delivered of a trisomy 18 infant. One trisomy 18 pregnancy was detected prospectively with maternal serum AFP, β-hCG, and unconjugated estriol among over 3000 women screened in 1990 (patient 14, Table I). These 14 singleton trisomy 18 pregnancies constituted the case group. The control group consisted of 285 randomly selected, previously screened women with known normal pregnancy outcomes. Demographic, pregnancy-specific, and AFP data were retrieved from the computer files and were used without further testing or modification. Gestational age had been based primarily on a woman's last menstrual period unless the gestational age calculated by ultrasonographic biparietal diameter was discrepant by >1 week. Case and control sera that were previously stored at −20° C were retrieved and analyzed for β-hCG and unconjugated estriol.

Laboratory methods. AFP was measured by radioimmunoassay with reagents from Clinical Assays. The sensitivity of the assay was increased by modifying the procedure to a two-step reaction and using a standard curve from 1.2 ng/ml to 60.5 ng/ml. The intraassay and interassay coefficient of variation at this low level was <5%. The AFP concentrations were converted to multiples of the normal median for gestational age on the basis of our own previous data and adjusted for maternal weight using previously published formulas.[7]

β-hCG was determined by a solid-phase, two-site im-

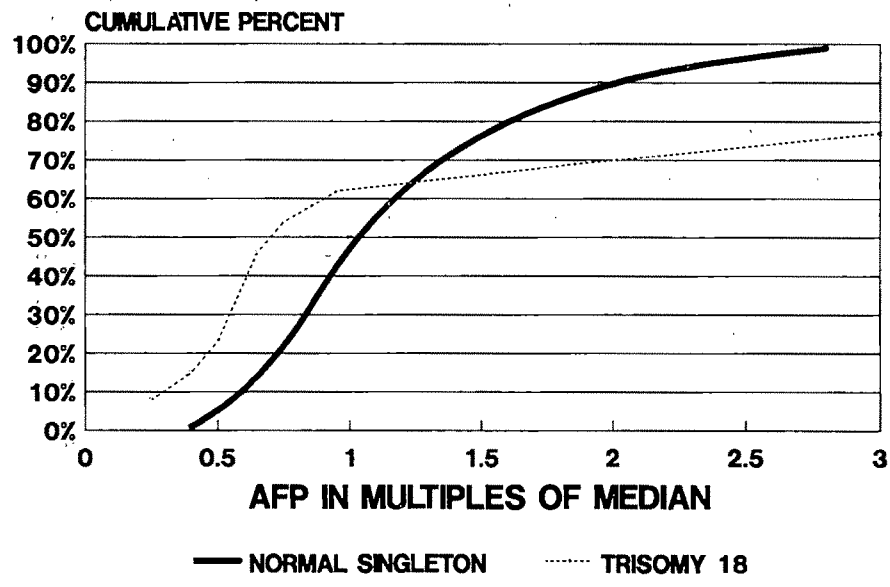

Fig. 1. Cumulative distribution maternal serum AFP levels of 13 trisomy 18 pregnancies and control singleton pregnancies by weight-adjusted multiple of the normal median.

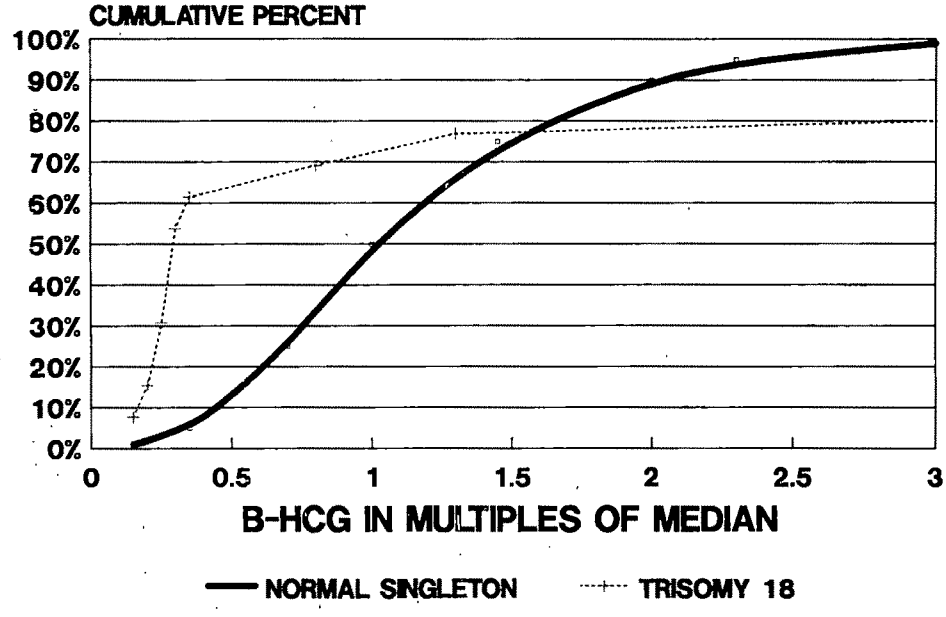

Fig. 2. Cumulative distribution β-hCG levels of 13 trisomy 18 pregnancies and control singleton pregnancies by weight-adjusted multiple of the normal median.

munoenzymatic assay (Tandem-E-HCG Immunoenzymatic assay kit, Hybritech, Inc.). Absorbance was recorded at 405 nm by means of a Photon-Immunoassay analyzer. Sera were diluted 1:500 for testing. Human sera containing β-hCG at 0 mIU/ml and 200 mIU/ml were used as standards.

Unconjugated estriol was determined by a solid-phase radioimmunoassay (Diagnostic Products Corp.). The procedure was modified to detect lower levels of unconjugated estriol at gestational ages <18 weeks. The concentrations of standards and controls ranged from 0.2 to 10 ng/ml. Iodine 125–labeled unconjugated estriol was reduced from 1.0 ml to 925 μl to maintain reaction volume, and controls were used at 1.0 and 5.0 ng/ml.

Results

The data from the 14 trisomy 18 cases are summarized in Table I. The mean gestational age was 16.3 weeks for cases and 17.2 weeks for controls. The mean

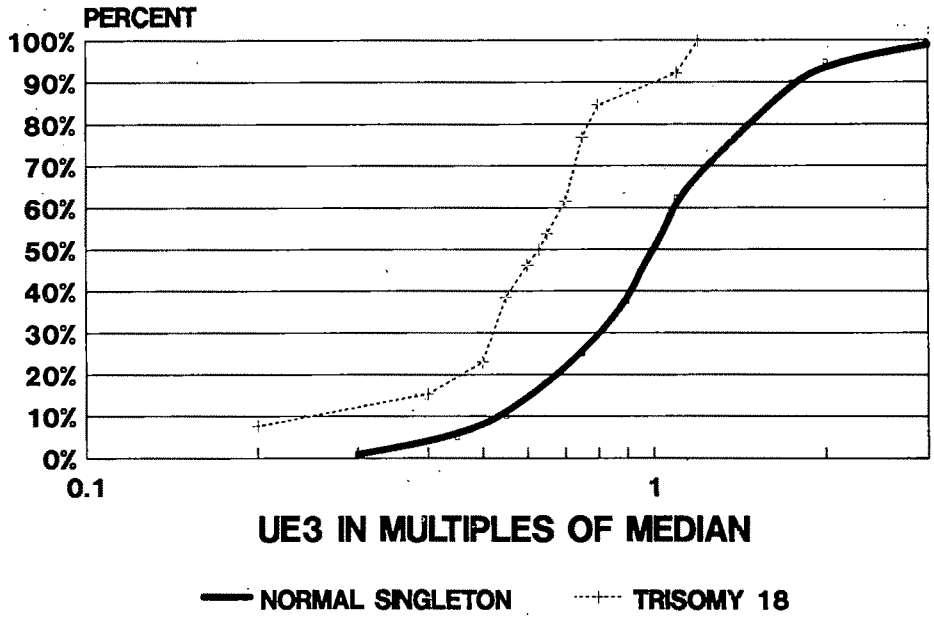

Fig. 3. Cumulative distribution unconjugated estriol levels of 13 trisomy 18 pregnancies and control singleton pregnancies by weight-adjusted multiple of the normal median.

maternal age for cases was 30 years, whereas the control mean was 28 years. The mean weight-adjusted AFP level for all controls was 1.05 multiples of the median. The mean weight-adjusted AFP level for the trisomy 18 pregnancies was 1.64 multiples of the median. The mean AFP level for trisomy 18 pregnancies without a neural tube defect or abdominal wall defect was 1.37 multiples of the median. The median AFP level for all trisomy 18 pregnancies was 0.95 multiple of the median and 0.65 multiple of the median for those without a neural tube defect or abdominal wall defect. The cumulative distribution of the 13 retrospective cases and controls is shown in Fig. 1.

After conversion of the β-hCG levels to weight-adjusted multiples of the median on the basis of the median for each week of gestation, the distribution of β-hCG levels for cases and controls was analyzed. The mean β-hCG multiple of the median for cases was 2.78 and was 1.00 for controls. However, the median β-hCG for the trisomy 18 pregnancies was 0.27 multiple of the median. For those trisomy 18 pregnancies without a neural tube defect or abdominal wall defect, the mean β-hCG was 3.70 multiples of the median and the median was 0.32 multiple of the median. The cumulative distribution of β-hCG levels for the retrospective cases and controls is shown in Fig. 2.

After conversion of the unconjugated estriol levels to weight-adjusted multiples of the median on the basis of the median for each week's gestation, the distribution of unconjugated estriol levels for cases and controls were analyzed. The mean unconjugated estriol multiple of the median for cases was 0.65 and was 1.00 for controls. For those trisomy 18 pregnancies without a neural tube defect or abdominal wall defect, the mean unconjugated estriol was 0.63 multiple of the median and the median was 0.56 multiple of the median. The cumulative distribution of unconjugated estriol levels for the retrospective cases and controls is shown in Fig. 3.

Comment

Fetal trisomy 18 has been known to be associated with low levels of maternal serum AFP in the second trimester.[1, 8] Low levels of maternal serum were observed in trisomy 18 pregnancies by Bogart et al.[3, 4] and confirmed by Norgaard-Pedersen et al.[9] Canick et al.[6] recently analyzed data from 10 trisomy 18 pregnancies and confirmed low levels of maternal serum AFP, β-hCG, and unconjugated estriol in those pregnancies. They found median levels of AFP to be 0.57, β-hCG to be 0.27, and unconjugated estriol to be 0.49 multiple of the median, respectively. None of these 10 pregnancies had open fetal defects (neural tube defect or abdominal wall defect). Among our 10 pregnancies without open defects, the median levels are 0.65, 0.32, and 0.56 multiple of the median for AFP, β-hCG, and unconjugated estriol, respectively. These data appear to be similar to that of Canick et al.[6] However, if we include the four trisomy 18 pregnancies with open defects, the median levels become 0.95, 0.27, and 0.67 multiple of the median for AFP, β-hCG, and unconjugated estriol, respectively.

Among our 14 trisomy 18 pregnancies, there were three with markedly elevated β-hCG levels. This anomaly has not been observed or reported previously and may represent placental abnormalities associated with the trisomic state. We recently became aware of at least

two other cases of trisomy 18 pregnancies with β-hCG elevations reported by Blitzer et al.[10] In addition, two of the four trisomy 18 pregnancies with abdominal wall defect had maternal serum AFP levels within the normal range (0.58 and 0.65 multiple of the median). Thus the low maternal serum AFP level associated with trisomy 18 may mask the presence of an open fetal defect. We have also observed a normal amniotic fluid AFP in one trisomy 18 pregnancy associated with an abdominal wall defect (detected by routine amniocentesis and ultrasound for advanced maternal age).

In their article Canick et al.[6] suggest a combined cutoff of 0.75, 0.55, and 0.60 multiple of the median for AFP, β-hCG, and unconjugated estriol, respectively, leading to a 0.4% false-positive (amniocentesis) rate and a 60% detection rate.[6] Applying their recommendations to our cases would have lead to a 29% detection rate. Because four of our cases had elevated maternal serum AFP levels and would have been detected for that reason, a total of eight trisomy 18 pregnancies (57%) would have been detected by the Canick method.[6] If, instead, we were to use cutoffs of 0.70, 0.40, and 0.70 multiple of the median for AFP, β-hCG, and unconjugated estriol, respectively, we would have detected five of the 14 (36%) trisomy 18 pregnancies with a 0.3% false-positive rate. Added to the four pregnancies with elevated maternal serum AFP, the detection rate would be 9 of 14 (64%). If elevated β-hCG levels (≥2.5 multiples of the median) were also used, the detection rate would rise to 11 of 14 (79%). Thus the method and efficiency of trisomy 18 screening prospectively using the three markers need to be evaluated further.

Ultrastructure of the microvasculature in the human endometrium throughout the normal menstrual cycle

Daniel K. Roberts, MD, PhD,[a] Tim H. Parmley, MD,[b] Nola J. Walker, EMSA,[a] and Douglas V. Horbelt, MD[a]

Wichita, Kansas, and Little Rock, Arkansas

In the early proliferative phase endometrial capillary basal lamina is loosely formed and discontinuous. It becomes more distinct in the late proliferative phase and develops whorled extensions that include pericytes in the early secretory to midsecretory phase. Throughout the cycle both endothelial cells and pericytes possess cytoplasmic processes that extend through discontinuities in the basal lamina and make contact with each other. These contacts may be simple or complex. They become more elaborate as the cycle progresses to the midsecretory phase. Endothelial cells show progressive but heterogeneous differentiation into the midsecretory phase, with individual cell hypertrophy. In the late-secretory phase the endometrial stroma and the basal lamina are characterized by widespread degeneration, and the cell-to-cell contacts sharply decrease. However, endothelial cells remain relatively intact. (Am J Obstet Gynecol 1992;166:1393-406.)

Key words: Human endometrial microvasculature, cell-to-cell interactions, pericytes, hypertrophy, endothelial cells

We have been interested in the morphologic ultrastructure of direct cell-to-cell contact in the human endometrium.[1,2] One place where such cell-to-cell contact might be expected would be in the endometrial microvasculature. Pericytes and endothelial cells are known to possess direct contacts in many other parts of the vascular tree.[3-5] Pericytes are known to have modulating effects on endothelial cell growth and differentiation,[5,6] and endothelial cell growth and differentiation

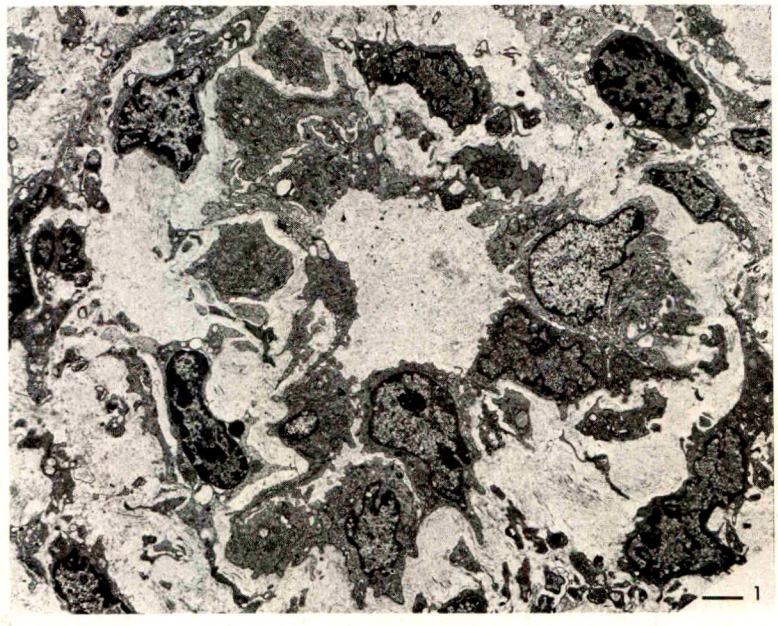

Fig. 1. Endothelial cells possess relatively little cytoplasm. They have smooth surfaces and the nuclear chromatin is clumped. (Original magnification ×3710. *Bar* 2.0 μm.)

Fig. 2. Developing Weibel-Palade bodies *(arrowheads)* are seen in association with Golgi. (Original magnification ×33,160. *Bar* 0.2 μm.)

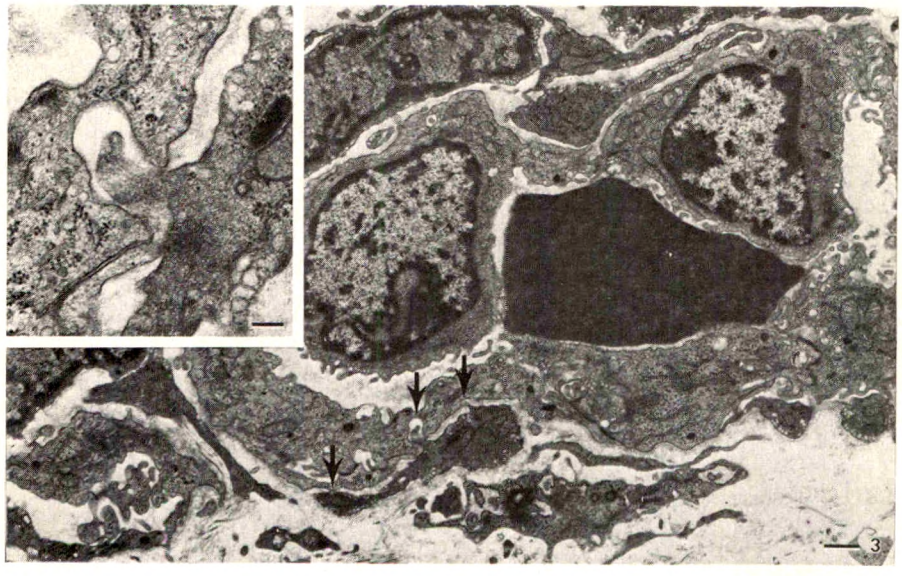

Fig. 3. Pericytes possess cytoplasmic extensions that make contacts with endothelial cells. The pericyte makes contact with adjacent endothelial cell at three sites *(arrows)*. presumably must take place cyclicly in the human endometrium.[7] Endothelial cell hypertrophy has also been described in experimental studies in endometrial capillaries.[8-11]

Therefore we studied pericyte-endothelial cell interactions and hypertrophy in the microvasculature of the human endometrium during the normal menstrual cycle.

Material and methods

Endometrial specimens were obtained by biopsy from normally menstruating women seen in the De-

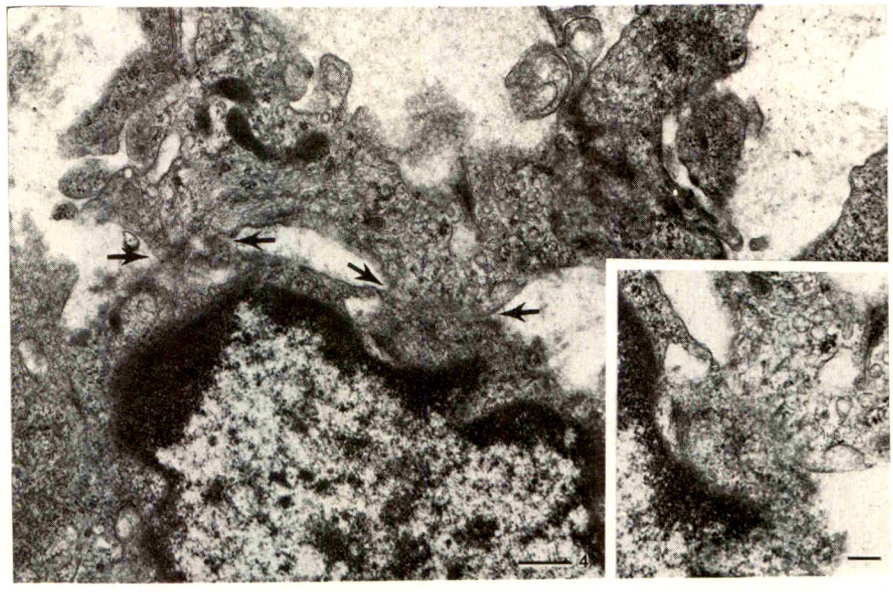

Fig. 4. An endothelial cell with intermediate filaments and pinocytotic vesicles makes diffuse contact with a pericyte at two points *(arrows)*. (Original magnification ×23,750. *Bar* 0.5 μm.) *Inset*, There is loss of definition of cell membranes approaching the site of contact, and filamentous structures appear to be continuous from one cell to the adjacent cell. (Original magnification ×30,375. *Bar* 0.2 μm.)

partment of Obstetrics and Gynecology at HCA-Wesley Medical Center during 1984 and 1985. Samples were obtained from five different women in each of the following phases of the cycle: early (days 5 to 9) and late (days 10 to 14) proliferative and early (days 15 to 19), middle (days 20 to 22), and late (days 23 to 28) secretory. None of the patients had received hormone preparations for 6 months before the biopsy procedure. Approximately half of each specimen was prepared for transmission electron microscopy. Hematoxylin and eosin–stained light microscopic samples were examined to confirm the presence of functionalis and to date the endometrial samples by the criteria of Noyes et al.[12]

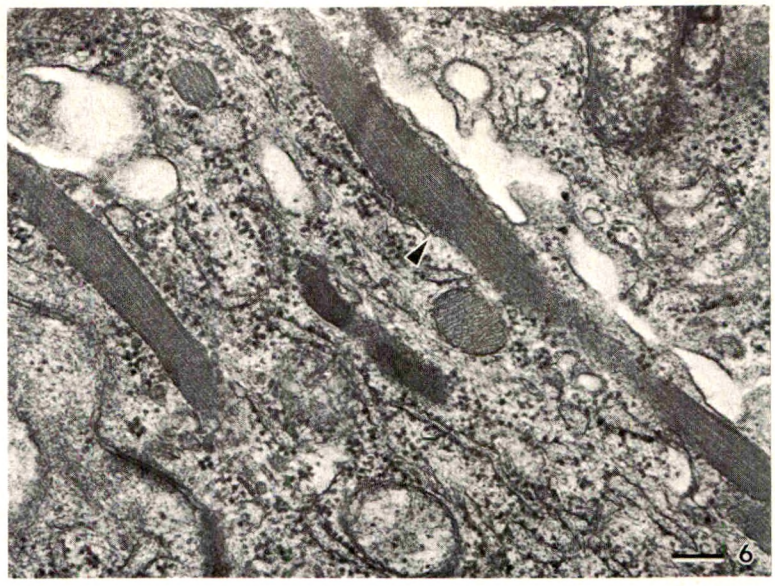

Fig. 6. More elaborate Weibel-Palade bodies *(arrowhead)* are seen in late proliferative phase endothelial cells. (Original magnification ×37,125. *Bar* 0.2 μm.)

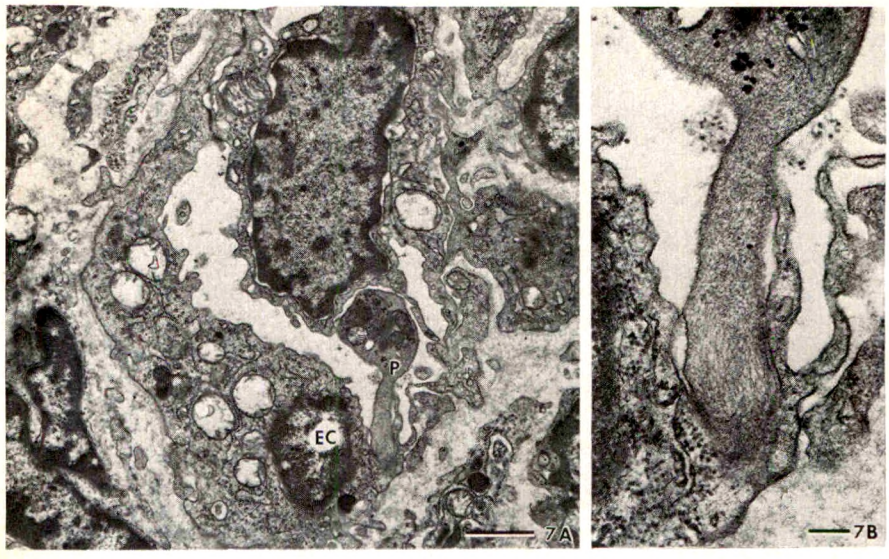

Fig. 7. A, In this late proliferative phase capillary a platelet *(P)* is attached to an endothelial cell *(EC)*. (Original magnification ×13,040. *Bar* 1.0 μm.) **B,** Attachment is characterized by loss of definition of cell membranes and dense filamentous connections. (Original magnification ×39,850. *Bar* 0.2 μm.)

Samples were prepared for transmission electron microscopy by routine methods.[13-16] Specimens were examined and photographed on a Philips 201 transmission electron microscope at magnifications ranging from ×3600 to ×121,000.

Initially, survey micrographs were taken of each sample, and capillaries were examined. Additional micrographs were taken, as required, to confirm the extent of an observation made in a given endometrium. A minimum of two tissue blocks (50 sections per block) were examined for each endometrial biopsy. Additional blocks were used as necessary to confirm the extent of any observed change.

Results

In the early proliferative phase nuclear chromatin in the endothelial cells is relatively condensed and the nuclei appear inactive (Fig. 1). Most of the endothelial

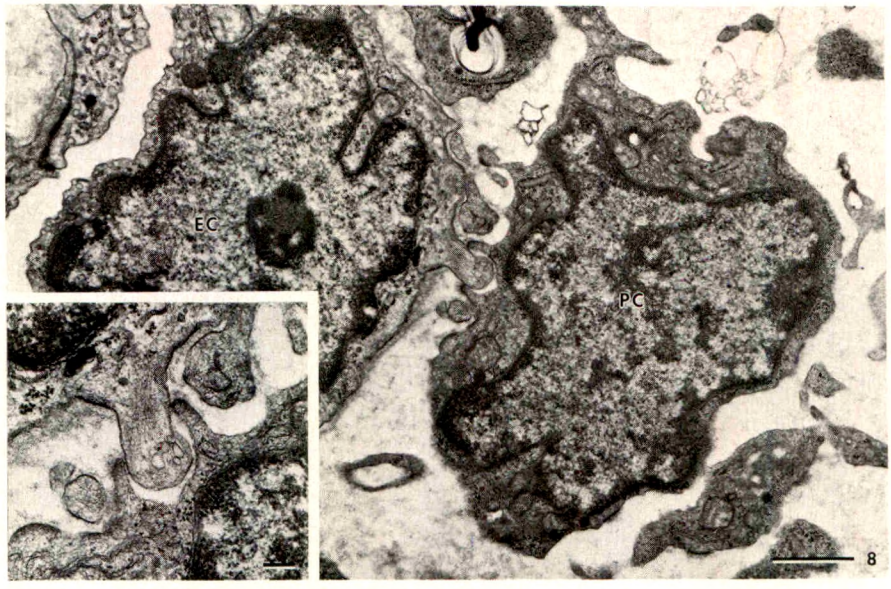

Fig. 8. This endothelial cell *(EC)* possesses a complex bulbous projection that contains both microfilaments and vesicles. The pericytic cell *(PC)* surface appears to be modified to accept this projection. (Original magnification ×16,200. *Bar* 1.0 μm.) *Inset,* The lips of the depression in pericytic cell surface make focal contact with shaft of endothelial cell projection.

cells possess only a small amount of cytoplasm, but they may be organelle rich. Weibel-Palade bodies, apparently arising from the Golgi apparatus, are present frequently (Fig. 2). There is a variable amount of Golgi and rough endoplasmic reticulum. Intermediate filaments and microfilaments are present. The luminal surface of the endothelial cells possesses only a few microvilli and is otherwise relatively smooth. Pinocytotic vesicles are common on both the basal and luminal surfaces. Endothelial cells are joined by tight junctions.

The stromal cells immediately surrounding the capillary, presumably pericytes, are of two types. One has large amounts of intracytoplasmic filaments and occasional dense bodies, thus resembling a smooth muscle cell. The other is fibroblastic in appearance. Both cell types have numerous pinocytotic vesicles. Vesicles are more frequent on the stromal surface of the smooth muscle–type cells.

The pericytes possess cytoplasmic extensions that project through the area of the basal lamina and make contact with the endothelial cells (Fig. 3, with inset). The capillary basal lamina is loosely formed and often discontinuous. Endothelial cells also possess cytoplasmic extensions that project through the area of the basal lamina to form connections with the pericytes.

These connections display varying degrees of intimacy. In some cases the cell membranes appear intact, and the site of contact consists of filaments connecting

Fig. 9. The lips of the cup-shaped depression are in contact with the base of pericytic cell cytoplasmic projection. The tip of the projection makes contact with the endothelial cell where pinocytotic vesicles apparently empty into the space containing the projection. (Original magnification ×47,250. *Bar* 0.2 μm.)

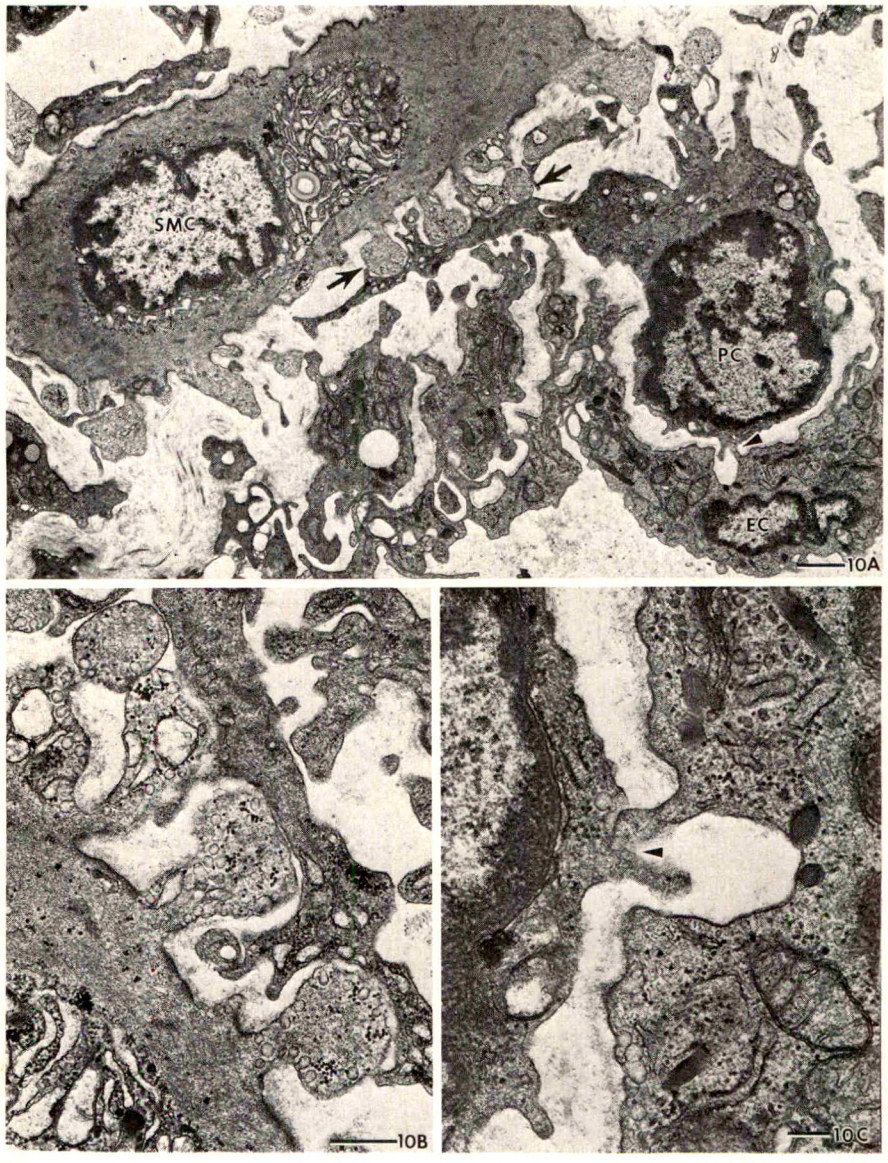

Fig. 10. A, Multiple cell-to-cell contacts *(arrows)* relate a smooth muscle–type cell *(SMC)* to a pericyte *(PC)*, which in turn makes contact *(arrowhead)* with an adjacent endothelial cell *(EC)*. (Original magnification ×9925. *Bar* 1.0 μm.) **B,** Numerous pinocytotic vesicles and glycogen granules occupy the tips of projections from smooth muscle–type cell. These tips appear to make contact with the pericyte. (Original magnification ×26,550. *Bar* 0.5 μm.) **C,** The pericyte also makes contact with endothelial cell *(arrowhead)*. (Original magnification ×40,500. *Bar* 0.2 μm.)

the two cell surfaces. Less commonly, the connections seem even more intimate, with cell membranes becoming indeterminate at the site of contact, and filaments in the cytoplasm of one cell are seemingly continuous with those in the cytoplasm of the adjacent cell (Fig. 4, with inset).

In the late proliferative phase many endothelial cell and pericyte nuclei become enlarged and are characterized by diffuse chromatin. Mitochondria are large and more numerous in both cell types. Rough endoplasmic reticulum is also more dilated and multiple Golgi possess more vesicles. In the endothelial cells both intermediate filaments and microfilaments are increased over the early proliferative phase (Fig. 5). Better-developed Weibel-Palade bodies are numerous (Fig. 6). Their relationship to the cell membrane is prominent.

Numerous platelets are seen in capillary lumina in

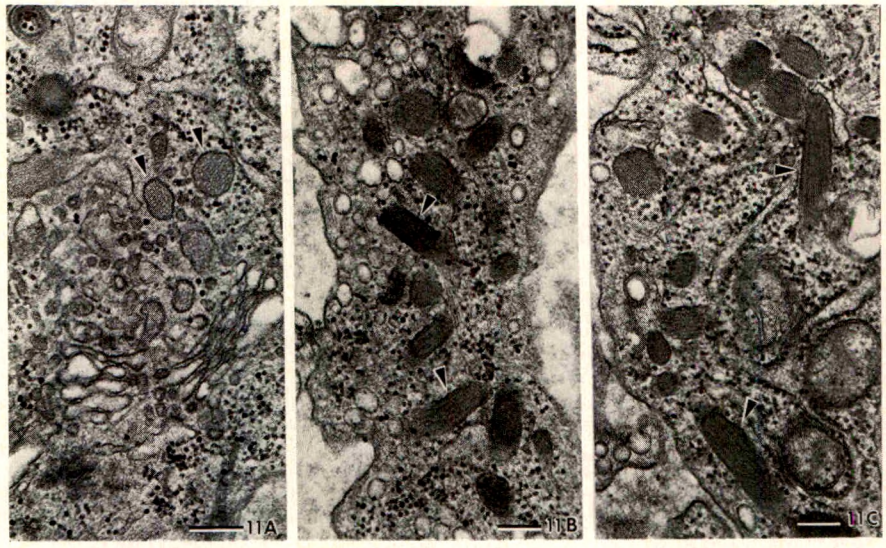

Fig. 11. A, Elaborate Golgi is closely associated with multiple Weibel-Palade bodies *(arrowheads).* (Original magnification ×22,570. *Bar* 0.5 μm.) **B** and **C,** Further stages of development in Weibel-Palade bodies are seen *(arrowheads).* (Original magnification ×42,070. *Bar* 0.2 μm.)

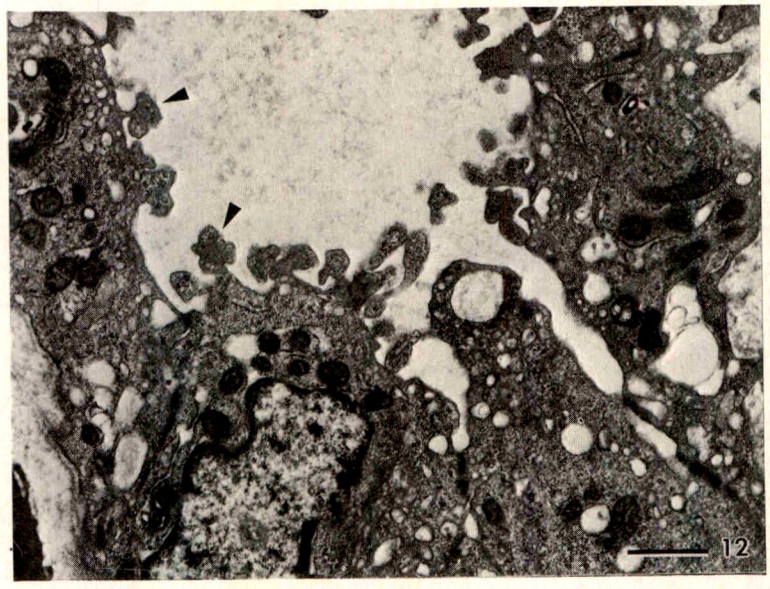

Fig. 12. Complex cytoplasmic blebbing *(arrowheads),* morphologically distinct from microvilli, characterize this endothelial cell surface. (Original magnification ×12,150. *Bar* 1.0 μm.)

the late proliferative phase. In one case an intraluminal platelet was seen to establish a fibrillar contact with an endothelial cell (Fig, 7, *A* and *B*). A search for fenestrations revealed one capillary with fenestrations in the basal lamina.

The pericytes are also more differentiated in the late proliferative phase. They possess enlarged nuclei with diffuse chromatin. Those pericytes that resemble smooth muscle cells are particularly prominent.

The capillary basal lamina is thickened and more diffuse than in the early proliferative phase. There is increased stromal collagen, which interacts with the endothelial basal lamina, pericytes, and surrounding stromal cells. Both the frequency and the complexity

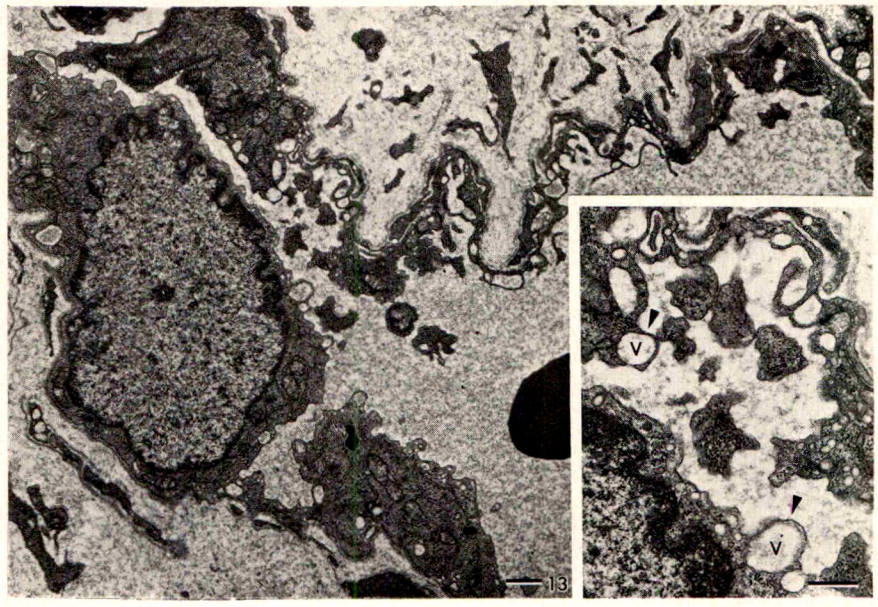

Fig. 13. Luminal surface of these capillary endothelial cells is characterized by microvilli, vacuoles, and surface blebs. (Original magnification ×7085. *Bar* 1.0 μm.) *Inset,* Pinocytotic vesicles are present but many of the large vacuoles *(V, arrowheads)* appear to be formed by microvilli that have folded back and fused with the cell surface. (Original magnification ×19,125. *Bar* 0.5 μm.)

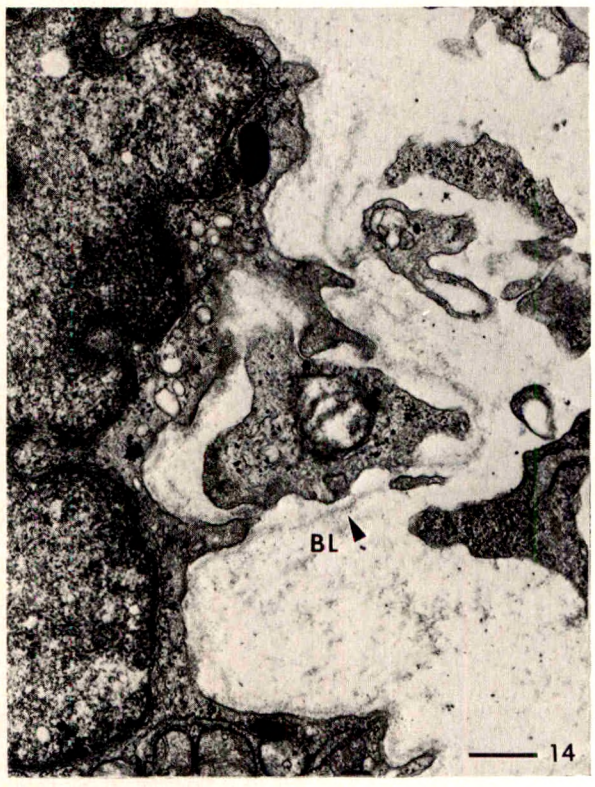

Fig. 14. Basal lamina *(BL, arrowhead)* is developing laminations and beginning to envelop a pericyte. (Original magnification ×20,200. *Bar* 0.5 μm.)

of direct connections between endothelial and pericytic cells appear to be increased. Endothelial cell cytoplasmic projections extend into indentations and make contact with stromal cells in a variety of ways. These were described in the early proliferative phase but have become more elaborately developed. For example, endothelial cell cytoplasmic projections may possess bulbous tips that appear to fit into indentations in the pericytic cell surface (Fig. 8, with inset).

Also, cytoplasmic projections from pericytic cells extend into the endothelial cell compartment through discontinuities in the basal lamina. The tip of the pericytic cell projection extends into the cup-shaped depression of the endothelial cell. There is often contact between the lips of the endothelial cell cup and the base of the pericytic cell projection (Fig. 9). Pinocytosis is often observed in the base of this cup-shaped depression. Heterogeneous connections are seen when a smooth muscle–type cell possessing a series of bulbous cytoplasmic projections fit into cytoplasmic indentations of an adjacent pericyte and in turn makes contact with an endothelial cell (Fig. 10, *A* through *C*).

In the early secretory phase of the cycle selected endothelial cells begin to experience cytoplasmic growth. This growth may occur in one endothelial cell and be absent in an adjoining cell. Where growth occurs, there are substantial increases in Golgi, rough endoplasmic reticulum, and vacuoles. The Golgi becomes more elab-

Fig. 15. Two of the endothelial cells in this capillary are dramatically enlarged with increased ribosomes and other organelles. Other endothelial cells in the capillary are apparently not participating in this process. (Original magnification ×7085. *Bar* 1.0 μm.)

orate and the rough endoplasmic reticulum begins to dilate. Weibel-Palade bodies in varying stages of development persist (Fig. 11, *A* through *C*). Both endothelial cells that enlarge and those that do not show increased surface blebbing (Fig. 12), microvilli, and vacuoles apparently formed by microvilli falling back onto the cell surface[17] (Fig. 13, with inset). Both cell types also seem to have less active nuclei than in the late proliferative phase, with more clumped chromatin and smaller size.

At the same time both the fibroblastic and smooth muscle–type pericytic cells participate in the morphologic process termed decidualization. An increased number of ribosomes, dilated rough endoplasmic reticulum, vacuoles, and more elaborate Golgi complexes develop, contributing to increased cell size. Light glycogen also appears. Basal bodies continue to appear in stromal cells and, in a few cases, cilia are formed. The pericytes resembling smooth muscle cells that contain large amounts of microfilaments and dense bodies are less apparent. They now possess many more cell organelles, and the filaments appear diluted.

The basal lamina becomes significantly more intact and also more complex. It begins to develop laminations and starts to envelop small pericytes (Fig. 14). Although the number of direct communications between endothelial and pericytic cells seems decreased in this phase, remaining connections are more elaborate.

In the midsecretory phase those endothelial cells that are enlarging have now done so, even more dramatically, and may almost fill a capillary space. This process remains heterogeneous (Fig. 15). Free ribosomes, mitochondria, dilated rough endoplasmic reticulum, and elaborate Golgi complexes are present. Weibel-Palade bodies are frequent and well developed in this phase, as are intermediate filaments. The endothelial surface is somewhat less complex.

The pericytic cells are even more decidualized than in the early secretory phase. Basal bodies are prominent and rare cilia are present.

The basal lamina becomes better defined than in any other time in the cycle. It is profusely elaborate with many additional lamina enveloping as many as two or three layers of pericytic cells (Fig. 16, *A* through *C*). Cytoplasmic interdigitations between endothelial cells and stromal cells are more evident than in the early secretory phase. In addition, larger surface areas of each cell are involved in these cell contacts (Fig. 17, with inset). More endometrial stromal cells consistent with the endometrial granulocyte are seen immediately adjacent to the capillary in a pericytic position (Fig. 18). Cell-to-cell interactions between this cell type and the endothelial cells are also seen (Fig. 18, inset).

In the late secretory phase there is widespread degeneration in the stromal compartment of the endometrium, consisting of extensive cellular fragmentation. The capillary basal lamina is much more fragmented. There is a marked decrease in the interactions between endothelial and pericytic cells.

However, the endothelial cells, in spite of apparent separations, are characterized by their contrast with the fragmenting cells in the stroma (Fig. 19). In many cases

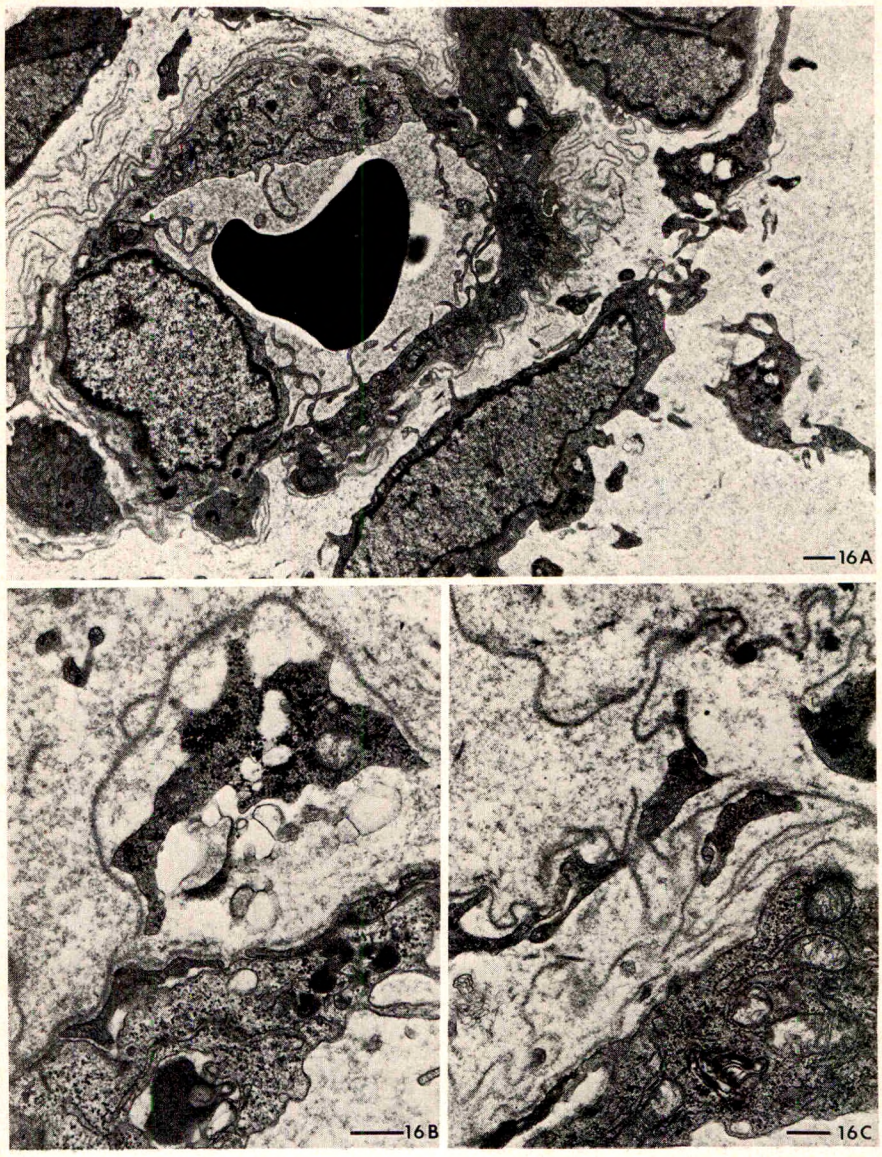

Fig. 16. Basal lamina possess many laminations, some of which envelop adjacent cells, whereas others are arranged as whorls in the extracellular space. (**A,** Original magnification, ×6900; *bar* 1.0 μm. **B,** Original magnification, ×22,450; *bar* 0.5 μm. **C,** Original magnification, ×17,225; *bar* 0.5 μm.)

the endothelial cells appear quite healthy and, in some instances, even more hypertrophied than in the midsecretory phase. There is an apparent increase in the number of free ribosomes, rough endoplasmic reticulum in long strands, and Golgi complexes. Frequently multiple small Weibel-Palade bodies are associated with this elaborate Golgi. Weibel-Palade bodies are often found at the tips of cytoplasmic projections, both into the lumen of the capillary (Fig. 20, *A*) and occasionally near the abluminal plasma membrane as well (Fig. 20, *B*). The endothelial cell surfaces show scattered microvilli, and fibrin is readily identified in the capillary lumen (Fig. 21, *A* and *B*). There is also an increased number of multivesicular bodies in the late secretory capillary endothelial cells. These bodies display heterogeneity of form and increased numbers.

Comment

This report, as well as two previously published, allows for a composite reconstruction of the ultrastructure of cell-to-cell contact in the human endometrium.[1,2] From the endothelial cell through stromal cells to the epithelium, the tissue is continuous. This includes the endometrial granulocyte that interacts with other endometrial cell types. The sites of contact are relatively small in the early proliferative phase. They increase in

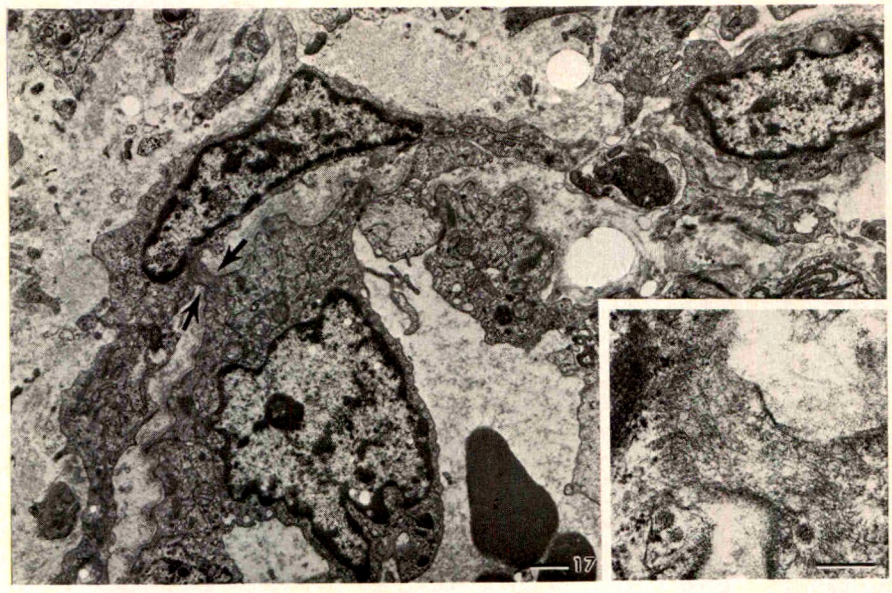

Fig. 17. An endothelial cell projection makes contact with a pericyte *(arrows)*. (Original magnification ×7950. Bar 1.0 μm.) *Inset*, Cell membrane definition is lost approaching this site, and filamentous structures appear to be continuous from one cell to another. (Original magnification ×45,350. *Bar* 0.25 μm.)

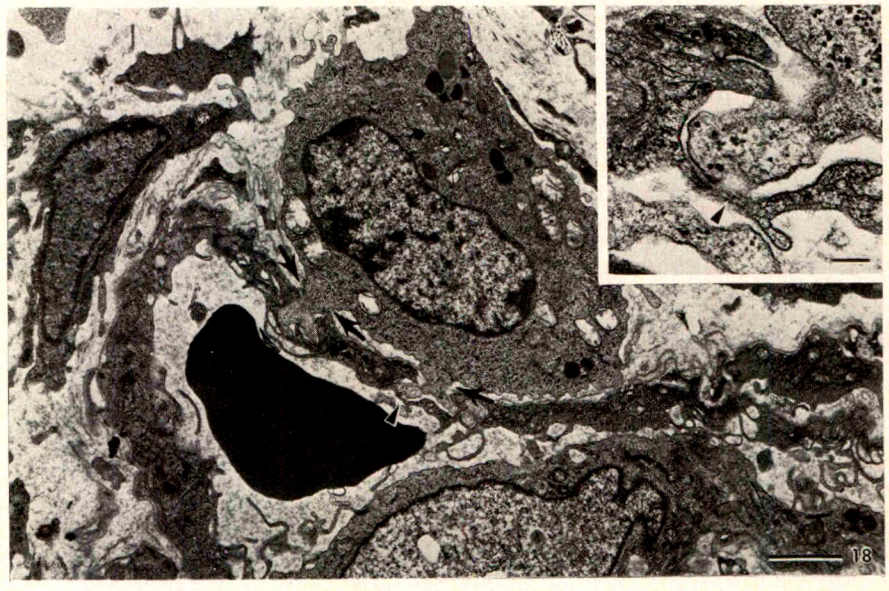

Fig. 18. This endometrial granulocyte, possessing both granules and a kidney bean–shaped nucleus, also possesses two cytoplasmic extensions into the endothelial cell compartment *(arrows)*. Both projections divide and become more complex as they enter the endothelial cell compartment. (Original magnification ×7250. *Bar* 2.0 μm.) *Inset*, One of the resulting papillae deeply penetrates the endothelial cell, forming close cell-to-cell contact *(arrowheads)*. (Original magnification ×37,125. *Bar* 0.2 μm.)

number and complexity and are extensive by the end of the proliferative phase. During the early and midsecretory phases connections between all microvascular cell types become more elaborate in structure and larger in size, although possibly they are less frequent. In the late secretory phase these connections become even less frequent.

A wide variety of evidence supports the idea that cell-to-cell contact is important in the control of differentiation. In mammalian embryos cells with similar de-

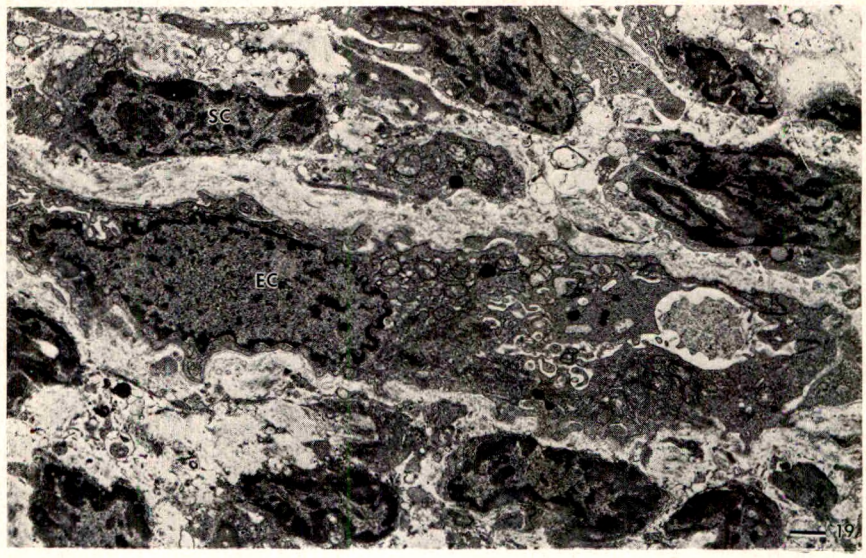

Fig. 19. Endothelial cells *(EC)* are substantially more intact than surrounding stromal cells *(SC)*. (Original magnification ×7085. *Bar* 1.0 μm.)

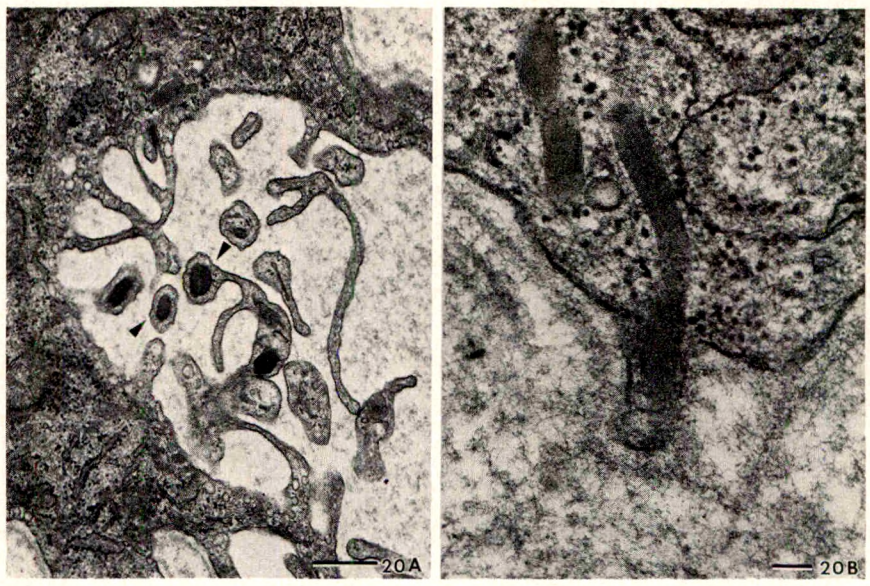

Fig. 20. A, Endothelial microvilli possess Weibel-Palade bodies *(arrowheads)* in the tips extending into the lumen of capillary. (Original magnification ×25,920. *Bar* 0.5 μm.) **B,** A Weibel-Palade body is also seen projecting through the abluminal plasma membrane. (Original magnification ×75,940. *Bar* 0.1 μm.)

velopmental fates remain connected by gap junctions, whereas those with divergent developmental fates lose these connections.[18] The induction of mesoderm from embryonic ectoderm by endoderm in the mouse is known to require close cellular proximity.[19] Pericytes modulate endothelial cell behavior and are most effective in this regard when in contact with endothelial cells.[6] Recently, epidermal growth factor has been demonstrated at the site of pericyte projections into endothelial cells.[20]

Endometrial epithelial cells are known to require endometrial stroma to display some types of normal behavior, including differentiation.[21-23] Consequently, it seems plausible that the coordinated growth and de-

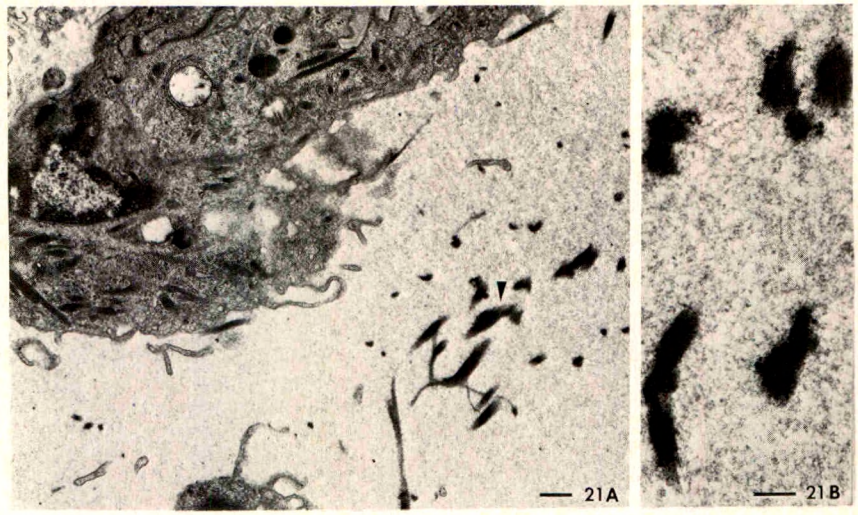

Fig. 21. A, Large amounts of fibrin *(arrowhead)* are present in this capillary lumen. (Original magnification ×6910. *Bar* 1.0 μm.) **B,** Fibrin is seen here at higher magnification. (Original magnification ×40,500. *Bar* 0.2 μm.)

velopment of the endometrium is, at least in part, supported by the extensive physical contacts that connect its component cell types.

Endothelial cell hypertrophy has been described in the endometrial capillaries of several primates, including human, at implantation sites.[8-11] Potential confusion of this phenomenon with the trophoblast invasion of vasculature at implantation sites described by Ramsey,[24] led Denker et al.[8] to perform an experimental study that excluded the trophoblast. When a silk suture and progesterone were combined in the endometrium of the rhesus monkey, endothelial cell hypertrophy was noted. Wilborn and Flowers[25] reported a similar change in the capillaries of the endometria of women receiving estrogen-progestin–containing oral contraceptives. We have seen endothelial cell hypertrophy in the endometrial capillaries of women during the luteal phase of the normal cycle. Therefore it seems logical to attribute this phenomenon to progesterone in combination with estrogen. One can only speculate about the function or functions of these cells, but it is now commonly accepted that endothelial cells are involved in many physiologic functions beyond simply lining the capillaries.[26]

A striking observation is that capillary endothelial cells seem quite healthy in late secretory endometria, in spite of considerable necrosis in the tissues around them. This would seem to support a continuous role for the capillaries in the phenomenon of menstruation. Wagner and Marder[27] used biochemical observations to substantiate the concept that Weibel-Palade bodies[28, 29] serve as storage or processing organelles for von Willebrand factor. In addition, it is believed that fibrin may be involved in von Willebrand factor release from Weibel-Palade bodies.[30] The increased activity in Weibel-Palade bodies and increasing amounts of intraluminal fibrin in late secretory endometrium may be evidence for their combined roles in menses. Determination of a relationship between von Willebrand factor and menstruation would be most interesting.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Stay at the forefront of your specialty! Subscribe today by returning the order form or by calling our toll-free number.

Chorionic villus sampling for fetal Rh typing: Clinical implications

T.S. Kickler, MD, K. Blakemore, MD, R.S. Shirey, MS, S. Nicol, BS, N. Callan, MD, P.M. Ness, MD, C. Escallon, MS, and G. Dover, MD

Baltimore, Maryland

OBJECTIVE: The prenatal Rh typing of red blood cells obtained by chorionic villus sampling was performed with an immune rosette technique.

STUDY DESIGN: Ten Rh-negative pregnant women undergoing chorionic villus sampling at 9 to 11 weeks' gestation were studied at a large referral hospital.

RESULTS: Accurate Rh phenotyping may be done on red blood cells obtained from chorionic villi weighing 2 to 8 mg. The preparations were shown to be >90% fetal in origin as demonstrated by radial immunodiffusion quantitation of fetal hemoglobin–containing cells. Of the 10 fetuses typed in the first trimester nine of the pregnancies were carried to term. In all cases typing of red blood cells confirmed the antenatal fetal red cell typing.

CONCLUSIONS: This study shows that antenatal Rh phenotyping may be performed as early as 9 to 11 weeks' gestation. This technique may be used in the management of pregnancies complicated by Rh incompatibility. (Am J Obstet Gynecol 1992;166:1407-11.)

Key words: Hemolytic disease of the newborn, chorionic villus sampling, prenatal diagnosis

Prenatal diagnosis of genetic disorders in the second trimester of pregnancy by amniocentesis is a well-established technique. The procedure was actually first used in 1950 for the obstetric management of Rh disease. Recently, chorionic villus sampling has evolved as a useful clinical procedure for the diagnosis of genetic disorders.[1] Chorionic villus sampling can be performed during the first trimester of pregnancy (9 to 12 weeks' gestation), with earlier test results allowing termination of pregnancy during this safer time period.

In spite of the standard use of Rh immune globulin prophylaxis in Rh-negative mothers with Rh-positive fetuses, Rh immunization still occurs. The management of fetuses at risk for severe hemolytic disease of the newborn requires intensive monitoring with amniocentesis and ultrasonography. Therapeutic measures include intrauterine transfusions, intravenous γ-globulin, plasmapheresis, and early delivery.[2] We show that chorionic villus sampling very early in pregnancy can reliably identify the Rh status of fetuses. This may lead to the improvement of antepartum management of immune hemolytic disease of the newborn.

Material and methods

Isolation of fetal red blood cells. Chorionic villus samples weighing 2 to 8 mg were obtained under ultrasonographic guidance in accordance with Johns Hopkins Maternal-Fetal Tissue guidelines and with the informed consent of the patient. Samples were collected from 10 Rh-negative mothers undergoing chorionic villus sampling at 9 to 11 weeks' gestation for genetic analysis. Blood samples were collected from the women before the procedure, and all women received Rh immunoglobulin prophylaxis after the procedure.

The chorionic villus samples were collected in Hanks' balanced salt solution (Gibco, Grand Island, N.Y.). Removal of surface-contaminating maternal red blood cells was done by gently washing the tissue in isotonic saline solution. The fetal red blood cells were then harvested by crushing the villi through a fine mesh screen suspended over a microtiter well (Immulon I Removawell, Dynatech Laboratories, Chantilly, Va.). The microwell was then placed in a 12 × 75 mm tube and the cells washed three times with saline solution. After each wash the saline solution was removed with a Pasteur pipet. The use of the microtiter wells facilitated handling of the 100 μl samples and reduced the risk of sample loss. We found that the villus samples stored at 4° C for 5 days in Hanks' balanced salt solution before processing still gave reliable results.

To validate that the harvested cells were of fetal origin, fetal hemoglobin-bearing blood cells were measured by a microscopic single-cell radial immunodif-

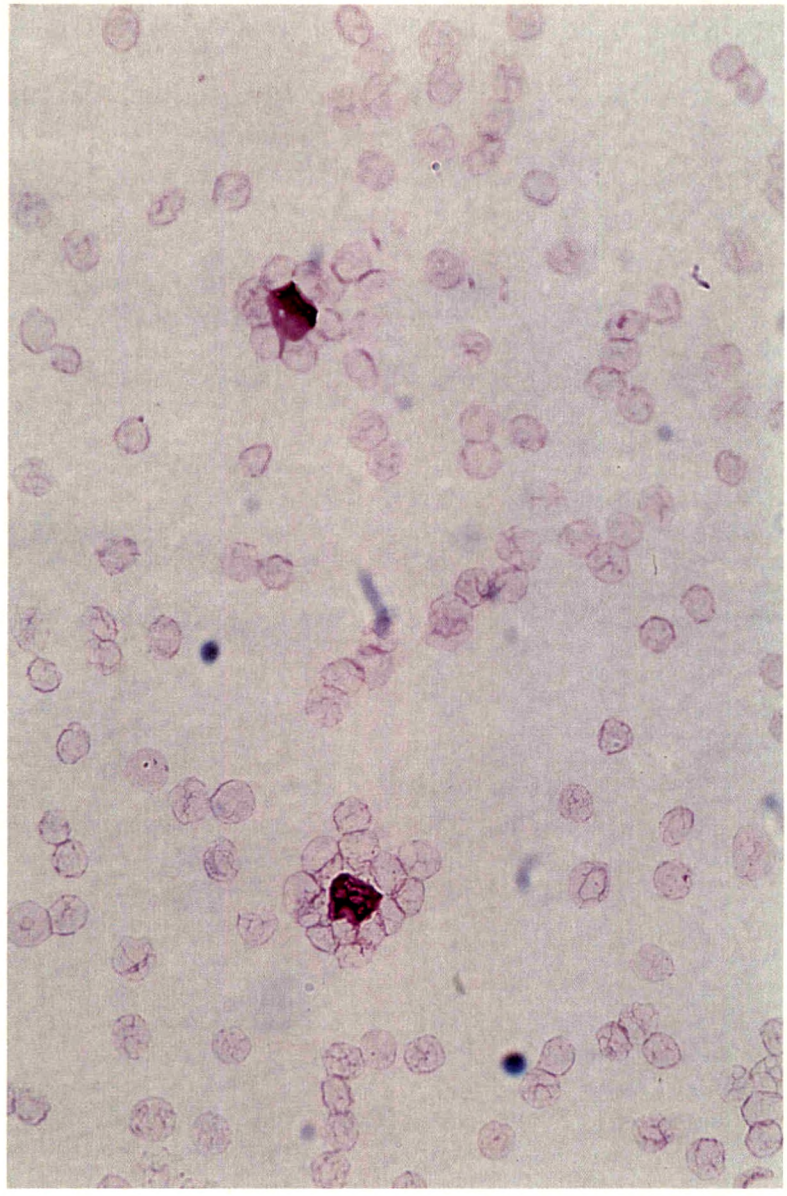

Fig. 1. Rosette that has been stained for fetal hemoglobin. In center of field is dark-staining fetal cell surrounded by pale-staining indicator cells.

fusion method using a rabbit antihuman fetal hemoglobin antibody.[3] Some preparations were stained for fetal hemoglobin with the F Cell Stain kit (Simmler, St. Louis).

Immune rosette test. To perform the immune rosette test, 50 μl of anti-D and 50 μl of papain (Organon Teknika Corp., Parsippany, N.J.) were added to the isolated fetal cells. Controls consisting of 1% suspensions of D-positive cells mixed with D-negative cells (0.5%, 0.25%, and 0%) were tested in parallel. The tests and controls were incubated at 37° C for 30 minutes and then washed six times with saline solution. After the addition of 50 μl of a 1% saline suspension of papain-pretreated D-homozygous (R_2R_2) cells and centrifugation, the cells were gently resuspended and placed on slides for microscopic observation.

The results are expressed as the number of rosettes per high-power field. At least one rosette per high-power field was the criterion of positivity. A rosette was defined as five or more indicator cells adherent circumferentially to a fetal red blood cell. Approximately 10 microscopic fields were examined by two independent readers.

Results

The number of red blood cells harvested per villus sample ranged from 10^6 to 10^8. Chorionic villus samples weighing as little as 2 mg yielded sufficient fetal red

blood cells for phenotyping. Storage of the villi at 4° C for 5 days in the culture media did not alter the yield of red blood cells.

The fetal origin of three cell preparations was determined with an immunoprecipitation method that measures the individual cell fetal hemoglobin contents. All samples showed >90% fetal hemoglobin–containing cells. The corresponding maternal blood samples showed <1% fetal hemoglobin–containing cells. These results confirmed that the test samples were not being contaminated with maternal red blood cells. This contamination could potentially result in the dilution of the Rh-positive fetal cells and a reduction in the diagnostic usefulness of the immune rosette test.

The sensitivity of the immune rosette test was assessed by making artificial cell mixtures of Rh-positive cells in Rh-negative cells. As few as one Rh-positive cell in 1000 Rh-negative cells could be detected.

In the Rh-positive fetuses between one and three rosettes per high-power field were seen. A typical rosette is shown in Fig. 1. To demonstrate that the indicator cells formed rosettes around fetal cells, a fetal hemoglobin stain was performed. The indicators cells are seen rosetting around the acid-resistant cells containing fetal hemoglobin.

Table I shows the results of the chorionic villus Rh typing and the Rh phenotype testing of cord blood after delivery of the infants at term. As shown, samples weighing as little as 2 mg yielded adequate numbers of red blood cells for typing. Ten chorionic villi samples were typed; however, one of the pregnancies was electively terminated, accounting for only nine cord blood typings. There were no discrepancies between the typing results performed antenatally and those determined from the cord blood sample.

Comment

Chorionic villus sampling enables one to obtain cells for prenatal diagnosis in the first trimester. Because the villi are derived from the fertilized ovum, they reflect the genotype of the developing fetus. The development of chorionic villus sampling has thus provided early assessment of the status of developing fetuses that may be at risk for a variety of genetic disorders.[4] Although chorionic villus sampling is a safe and effective technique for early prenatal diagnosis, there may be a slightly higher risk of fetal loss than with second-trimester amniocentesis.[5]

Shortly after the institution of chorionic villus sampling, it was recognized that the capillary vessel coursing through the long axis of the villus would be an ideal source of fetal red blood cell cells. This observation was then applied to fetal Rh typing.[6] Rh typing of red blood cells from chorionic villi may serve three purposes: (1) for early fetal phenotyping in women with a history of severely affected infants with hemolytic disease of the newborn and wishing to terminate the pregnancy if the fetus is Rh positive, (2) as an alternative to cordocentesis done in the second trimester in the Rh-immunized woman with previously affected fetuses and wishing to continue with the pregnancy, and (3) in determining the need for Rh prophylaxis in Rh-negative, nonimmunized women undergoing chorionic villus sampling for genetic analysis.

The first application for fetal Rh typing is in severe immunization when the father is an apparent Rh heterozygote. Knowing the fetal Rh phenotype early in gestation may help such couples to decide whether they wish to continue the pregnancy. Before performing the procedure, one must consider that the procedure itself may lead to an increase in the antibody titer, increasing the chances of, and perhaps the severity of, intrauterine hemolysis if the fetus is Rh-positive. If severe fetal anemia develops earlier than 18 weeks of gestation after first-trimester chorionic villus sampling in a previously immunized patient, fetal intrauterine transfusion may be technically very difficult.[7]

Prospective studies about the potential risk of worsening immunization by first-trimester chorionic villus sampling have not been performed. In the report by Kanhai et al.[8] two of eight women severely immunized against Rh or Kell antigens elected to continue their

pregnancies after first-trimester chorionic villus sampling revealed the fetus to be positive for the red blood cell antigen in question. One patient whose fetus was Kell positive by chorionic villus sampling at 9 weeks required four intrauterine transfusions between weeks 23 and 31. The second patient required three intrauterine transfusions and was delivered of an Rh-positive infant at 35 weeks. Both women also underwent weekly plasmapheresis. The two babies did well. Whether the course of fetal disease was altered detrimentally by chorionic villus sampling is unknown, but neither woman produced a significant rise in antibody titers after the procedure. There are three occurrences of immune hydrops fetalis in the midtrimester of pregnancy after first trimester chorionic villus sampling on previously immunized patients (Moise, personal communication).[9] This potential risk warrants extensive patient counseling before performing early chorionic villus sampling in immunized women. Removing as small a villus sample as possible with the fewest number of passes may minimize the risk of significant fetomaternal hemorrhage.[10] Because the immune rosette method described in this report requires <10 mg of villi, the number of potentially immunizing red blood cells may be low enough to avoid such a consequence.

Many women may wish to undertake a pregnancy in spite of very severe Rh immunization. In these cases, where the father is an apparent D heterozygote, second trimester Rh phenotyping of the fetus is often desirable. At this gestational age chorionic villus sampling may be a useful alternative to cordocentesis for Rh phenotyping. Because cordocentesis is frequently performed by traversing the placenta to reach the umbilical cord insertion site, a large amount of fetomaternal bleeding may be expected to occur. Nicolini et al.[11] found that the mean estimated volume of fetomaternal hemorrhage associated with intravascular intrauterine transfusion by cordocentesis was 2.4 ml of fetal blood and furthermore that both the maternal antibody concentration and the rate of fall in fetal hematocrit was greater when the hemorrhage was >1 ml. A greater incidence of fetomaternal hemorrhage occurred when the placenta was anterior.

If chorionic villus sampling were performed as an alternative to cordocentesis, the risk of fetomaternal hemorrhage could be potentially reduced. From several reports of maternal serum α-fetoprotein rises before and after either cordocentesis or chorionic villus sampling, it appears that second and third trimester chorionic villus sampling may result in a lower incidence of significant maternal serum α-fetoprotein rises than does transplacental cordocentesis.[11-14] We have begun to examine villus samples at these later stages of gestation. Our preliminary findings on 12 samples collected from 17 to 40 weeks of gestation also indicate that these samples yield abundant fetal red blood cells for phenotyping.

Studies of the increase in maternal serum α-fetoprotein concentrations before and after first trimester chorionic villus sampling suggests that associated fetomaternal hemorrhage can occur. In some cases the volume of fetomaternal bleeding may be sufficient to cause primary isoimmunization but has yet to be proven. Therefore a consensus for giving Rh immune globulin for chorionic villus sampling has not been established. However, considering the chance for immunization and the low risk of Rh immune globulin administration prophylaxis, the use of Rh immune globulin after chorionic villus sampling is recommended by the American College of Obstetricians and Gynecologists.[7]

By typing the fetal red cells in Rh-negative women undergoing villus sampling for genetic evaluation of the fetus, it may be possible to avoid giving unnecessary Rh immune globulin prophylaxis if the fetus is Rh negative. Our results show that even early in pregnancy sufficient red blood cells can be collected for accurate Rh phenotyping.

The ability to obtain sufficient red blood cells from the smallest possible amount of chorionic villus is especially important in minimizing the risk of isoimmunization. In studies by Blakemore et al.[10] there was a positive correlation between the volume of fetal blood transferred and the weight of the chorionic villus sample. When samples weighing <10 mg were obtained, only 21 μl of fetal blood was transferred. It is unlikely this small volume of red blood cells would cause primary immunization.

The major limitation of typing fetal red blood cells from chorionic villi is the small number of red cells present. This makes standard agglutination techniques for red blood cell typing difficult to perform. Using immunofluorescence, previous investigators have shown that fetal red blood cell phenotyping from villus samples in the first trimester of pregnancy is feasible. However, a relatively large sample size was required (25 to 40 mg of villi) to obtain sufficient red blood cells for testing.[15]

To reduce the size of the chorionic villus sample needed for testing, we applied a simple immune rosette procedure for phenotyping fetal red blood cells, a procedure that could be performed by any laboratory familiar with standard immunohematologic testing. This immune rosette procedure is similar to that reported by Sebring and Polesky[16] for use in the detection of fetal maternal hemorrhage in Rh immune globulin candidates. Importantly, chorionic villus samples weighing as little as 2 mg give reliable results.

The series of patients we report were not Rh immunized. Because the rosette test will be applied to women with anti-D, we have subsequently applied the

rosette technique to three pregnancies complicated by anti-D alloimmunization. We have found that the fetal cells are typable as Rh(D) positive when anti-D is present in the patient's sample. We also prepared mixtures of Rh(D)-negative cells and Rh(D)-positive fetal cells sensitized with anti-D. In these experiments, we found that the Rh(D)-positive fetal red blood cells could be accurately typed by the rosette technique. Therefore we do not believe that the presence of anti-D will interfere with accurate Rh phenotyping of fetal red blood cells by the rosette technique.

In summary, our studies show that fetal red blood cells harvested from chorionic villus samples early in pregnancy can be accurately Rh-typed by an immune rosette method. These results will be useful in the management of pregnancies complicated by Rh immunization and may also reduce the need for unnecessary Rh immune globulin prophylaxis in Rh-negative women undergoing chorionic villus sampling.

Infertility and pregnancy outcome in an unselected group of women with insulin-dependent diabetes mellitus

Karen Kjaer, MD, Claus Hagen, MD, Steen H. Sandø, MD, and Ole Eshøj, MD
Odense, Denmark

OBJECTIVES: The null hypothesis of this study is that infertility and pregnancy outcomes in women with insulin-dependent diabetes are identical to those of nondiabetic control subjects.
STUDY DESIGN: A questionnaire survey comprising an unselected population of 18- to 49-year-old diabetic women and a comparable control group was performed. Reply rates were 94% (n = 245) and 88% (n = 253), respectively.
RESULTS: Cumulative rates of pregnancies and involuntary infertility (17%) did not differ between the two groups. Diabetic women had significantly fewer pregnancies (1.4 vs 1.7) and fewer births per pregnancy than controls, and more diabetic women were nulliparous (48% vs 38%). Half of all diabetic pregnancies were planned. Diabetic women reported that their diabetes had a negative influence on their attitude toward having children.
CONCLUSION: In insulin-dependent diabetic women the ability to conceive is normal, but diabetic women have fewer pregnancies and fewer births per pregnancy than controls. (Am J Obstet Gynecol 1992;166:1412-8.)

Key words: Epidemiology, infertility, pregnancy outcome, insulin-dependent diabetes mellitus

In the preinsulin era the occurrence of pregnancy in women with diabetes mellitus was unusual, partly because of high mortality among these patients but also because of impaired fertility in the sexually mature diabetic woman. Estimates of fertility were about 2% that of nondiabetics.[1] After the introduction of insulin therapy, life expectancy for the diabetic women increased and fertility improved. Thus Bergqvist[2] reported that from 1938 to 1952 the pregnancy rate was estimated to be 38% lower in women with diabetes than in nondiabetics. Recently it has been reported that diabetic women have the same rate of spontaneous conception and sterility as controls.[3] During the last two decades several studies have been published concerning the prognosis of pregnancy outcome in diabetic women. However, studies on fertility and outcome of pregnancies in women with diabetes have so far comprised selected groups of women, often hospitalized patients.[2-4] In a recent population study from Aberdeen only 62% of infertile women attended a hospital clinic for treatment of their infertility,[5] and in a survey on infertility from Denmark less than half the women with reduced fertility had sought medical care.[6] These results clearly indicate that population-based studies are needed if meaningful data on infertility rates are to be obtained.

The aim of this study was to investigate the epidemiologic features of infertility and pregnancy outcome in an unselected group of women with insulin-dependent diabetes mellitus. For comparison an age-comparable, unselected group of nondiabetic women was included.

Material and methods

The study was performed in the County of Funen, which has approximately 450,000 inhabitants, constituting roughly 9% of the Danish population. With regard to demographic and socioeconomic status, the population of the county is representative of the Danish population as a whole,[7] and the area is therefore suitable for epidemiologic investigation on unselected patient populations.

Patient identification. From Sept. 1, 1986, to Aug. 31, 1987, all insulin-treated patients living in the County of Funen were identified by the prescription method.[7] All women between 18 and 49 years of age with onset of diabetes before the age of 30 years and who lived in the county on July 1, 1987, were identified (N = 281) (Table I). During the period Feb. 1, 1987, to Jan. 31, 1990, all but 20 who were excluded (10 had left the county, four had died, four had mental retardation, one had non–insulin-dependent diabetes mel-

Who gave information on fertility and who had attempted or experienced a first pregnancy	131	182
Who gave information on fertility and who had attempted or experienced a second pregnancy	83	145

litus, and one had aphasia after stroke) received a questionnaire comprising 31 main questions and 89 secondary questions. The questions related to the current survey concerned social status, time of diabetes onset, gynecologic history, present and previous desire for conceiving, number of pregnancies, and pregnancy outcome. The response rate of the 261 diabetic women entering the study was 94% (Table I). Median age of responders was 32 years (range 18 to 49 years), and median duration of diabetes 17 years (range 2 to 43 years). Of the responders 169 (69%) women were selected with a table of random numbers for more intensive investigation. Fasting C-peptide (radioimmunoassay method)[8] obtained from 163 of these 169 women was <0.20 nmol/L in 159, whereas four subjects had values between 0.22 and 0.40 nmol/L. In 44 women diabetes developed after their first pregnancy, and these women were secondarily excluded from the current study (Table I).

A group of nondiabetic women ($N = 289$), matching the diabetic women with regard to number and age distribution, was used as controls (Table I). The sample was drawn at random with a random number generator from the computerized Electronic Data Processing Department of Odense University Hospital, where all citizens in Funen County, whether healthy or ill, are registered. Two subjects were primarily excluded because of cancer. The response rate was 88%.

There were no significant differences between diabetic and control subjects with regard to marital status (75.1% diabetic and 76.7% control subjects were married), education, or occupation. In the group of 18- to 39-year-old subjects median age for the diabetic women was 28 years versus 29 years among controls ($p > 0.05$). In the 18- to 49-year-old subjects diabetic women were significantly younger than controls (median 31 years vs 33 years, respectively, $p < 0.03$).

Definitions of fertility groups. Infertility is defined as failure to conceive after attempting for >1 year. Primary infertility refers to the first pregnancy regardless of whether a pregnancy was eventually achieved. Secondary infertility refers to any subsequent pregnancy. Those women who conceived after attempting for ≤12 months are defined as having no fertility problem and are herein referred to as being fertile. Voluntary infertility refers to women never attempting pregnancy and never being pregnant. According to their history of fertility, the women were divided into three groups: those with infertility, primary or secondary; those with no fertility problem; and those with voluntary infertility. The women with primary or secondary infertility were subdivided into two groups: those with primary infertility, including those who also reported secondary infertility, and those with secondary infertility only.

Definition of planned or unplanned pregnancy. If pregnancy was desired and attempted, the pregnancy was reported as being planned, and if not, as being unplanned.

Statistics. Group comparisons concerning age were analyzed by the Mann-Whitney U test. Comparisons of fertility, number of pregnancies, and outcome of pregnancies were performed with the χ^2 test.

The study had the approval of the local ethics committee.

Results

Prevalence of infertility. One woman in the diabetic group and six women in the control group did not wish to give information concerning previous desire for pregnancy, which leaves 200 diabetics and 247 controls for investigation (Table I). Table II shows the number and prevalence rates of the different fertility groups. In tables and text the data shown in parentheses after the prevalence rates are 95% confidence limits.

There was no fertility problem in 54.5% of the diabetic women and 61.5% of the controls ($p > 0.05$). The median age of these diabetic women was 33 years, range 19 to 49 years, and for the controls 34 years, range 18 to 49 years ($p > 0.05$). A first pregnancy had been attempted or experienced by 131 diabetic women and 182 controls. The prevalence of no fertility problems

in these women was 83.2% and 83.5%, respectively ($p > 0.05$).

Voluntary infertility was reported by 34.5% of diabetic women and 26.3% of controls ($p = 0.06$). The median age of these women was 24 years, range 18 to 49 years for the diabetic women and 22 years, range 18 to 49 years for the controls ($p > 0.05$). In the age group 18 to 29 years, 48 of 91 (52.7%, 47% to 69%) diabetic women were voluntarily infertile versus 59 of 99 (59.6%, 49% to 69%) controls ($p > 0.05$). Among 30- to 49-year-old diabetic women, 21 of 109 (19.3%, 12% to 28%) were voluntarily infertile versus 6 of 148 (4.1%, 1% to 9%) corresponding controls ($p < 0.005$). The proportion of married subjects in the two groups was similar (56%).

Primary or secondary infertility had been experienced by 11.0% of the diabetic population and 12.1% of the control population. Median age of these women was 31 years, range 23 to 41, for diabetic women and 37 years, range 25 to 49, for controls ($p < 0.02$). The prevalence of primary or secondary infertility in women attempting or experiencing a first pregnancy was 16.8% in diabetic women and 16.5% in controls ($p > 0.05$). Five of 131 (3.8%, 1% to 9%) diabetic women had an unresolved infertility problem versus 13 of 182 (7.1%, 4% to 12%) controls ($p > 0.05$).

Of the diabetic women 14 of 131 (10.7%, 6% to 17%) had primary infertility only and three of 131 (2.3%, 0% to 7%) had both primary and secondary infertility. Of the controls 14 of 182 (7.7%, 4% to 13%) had primary infertility only and five of 182 (2.7%, 1% to 7%) had both primary and secondary infertility ($p > 0.05$).

A second pregnancy had been attempted or experienced by 83 diabetic women and 145 controls. The prevalence of secondary infertility only among these women was 6.0% in diabetic women and 7.6% in controls ($p > 0.05$).

Unplanned or planned pregnancies and cumulative rate of pregnancies. Among diabetic women and controls significantly more pregnancies were unplanned in the fertile group of women than in the infertile group, 114 of 219 (52.1%, 45% to 59%) versus eight of 42 (19.0%, 9% to 34%) for diabetic women ($p < 0.001$) and 201 of 365 (55.1%, 53% to 64%) versus nine of 44 (20.5%, 10% to 35%) for controls ($p < 0.0005$). There were no significant differences between diabetic women and controls when the same fertility groups are compared. The pregnancies took place between 1959 and 1989 for the diabetic women and controls. From 1959 to 1969 13 of 33 (39.4%, 23% to 58%) of the diabetic pregnancies were planned. The value from 1970 to 1979 was 56 of 113 (49.6%, 40% to 60%) and from 1980 to 1989 70 of 122 (57.4%, 49% to 67%). Thus the diabetic women had 139 of 261 (53.3%, 48% to 60%) planned pregnancies versus 199 of 409 (48.7%, 45% to 55%) in controls. The cumulative rate of these pregnancies (Fig. 1) did not differ significantly between diabetic women and controls. Thus after 1 year the fertility rate was 85% for the diabetic group and 88% for the controls. When the cumulative rate of pregnancies of the fertile diabetic women is compared with that of the fertile controls, no difference was found ($p > 0.05$).

Pregnancy rate and outcome of pregnancies. All diabetic women gave information on the outcome of pregnancies, whereas two of the controls declined. The median maternal age for the first pregnancy was 23 years, range 16 to 32 years, for the diabetic women and 23 years, range 15 to 40 years, for the controls. All the diabetic pregnancies and all but two of the control pregnancies took place when the women were between 18 and 39 years old.

Table III shows the pregnancy rate and pregnancy outcome for all pregnant women and for each fertility

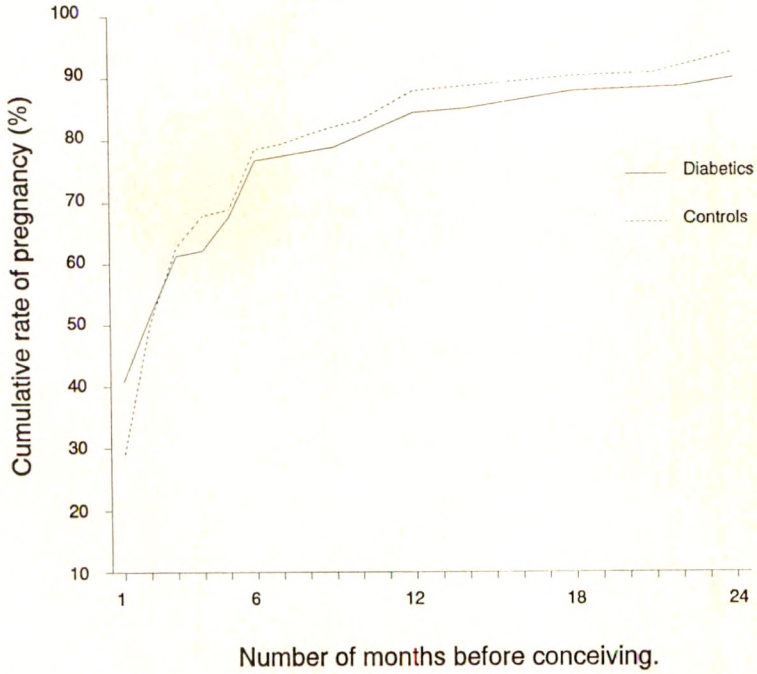

Fig. 1. Cumulative rate of pregnancy (time to conception) over months for 139 diabetic pregnancies and 199 control pregnancies (1959 to 1989).

group. The fertile and infertile diabetic women were significantly younger than corresponding controls (median 33 years, range 19 to 49 years versus 35 years, range 18 to 49 years, respectively) ($p < 0.003$). After the number of pregnancies for this age difference is adjusted, there is no significant difference in the number of pregnancies per fertile plus infertile woman in the two groups. For all the diabetic and control subjects surveyed, the pregnancy rate was significantly lower in the diabetic group (mean 1.3 and adjusted for age mean 1.4) compared with the control (mean 1.7) ($p < 0.01$ for both comparisons). Overall birth rate was lower in diabetic women compared with controls (69.5% vs 76.5%, $p < 0.05$). The infertile diabetic women had a lower birth rate ($p < 0.05$) and a higher spontaneous abortion rate ($p < 0.005$) compared with fertile diabetic women.

Cesarean section rate. The overall rate of cesarean sections was 82 of 182 (45.1%, 38% to 53%) in diabetic women and 39 of 322 (12.1%, 9% to 17%) in controls ($p < 0.001$). The rate in infertile diabetic women was 11 of 23 (47.8%, 27% to 69%) versus eight of 33 (24.2%, 11% to 42%) in controls ($p = 0.07$). For the fertile diabetic women the rate was 71 of 158 (44.9%, 37% to 52%) and for the fertile controls 31 of 277 (11.2%, 8% to 16%) ($p < 0.001$).

Number of births per woman. Significantly more diabetic women had no children, 96 of 201 (47.8%, 41% to 56%) compared with controls 94 of 251 (37.5%, 32% to 47%) ($p < 0.03$) and significantly fewer diabetic women had two or more children, 58 of 201 (28.9%, 23% to 36%) versus 118 of 251 (47.0%, 41% to 54%) for controls ($p < 0.01$).

Influence of the diabetes on the attitude toward having children. The diabetic women were questioned whether their diabetes had an influence on their attitude toward having children. Of the 197 who answered the question, 111 (56.3%, 47% to 62%) women gave a positive answer. Seventy-six (38.6%, 31% to 45%) were concerned about possible complications during pregnancy and delivery, 64 (32.5%, 26% to 39%) were concerned about an aggravation of diabetic control during the pregnancy, 57 (28.9%, 22% to 35%) were concerned about the risk that diabetes might develop in the child, 26 (13.2%, 9% to 19%) reported that the strain of daily diabetes care had a negative influence on their attitude toward having children, and 26 (13.2%, 9% to 19%) mentioned other reasons. In the voluntary infertility group, significantly more women, 47 of 67 (70.1%, 58% to 81%) gave a positive answer to the question compared with the rest, 64 of 130 (49.2%, 40% to 58%) ($p < 0.03$).

Comment

In general, the presence of infertility is considered psychologically distressing by most women, and much attention has therefore been directed toward identification and treatment of this problem. In the diabetic population infertility may add to the social strain of daily diabetic care and to potential diabetic complications. In these women early discovery of an infertility problem is especially important, because advanced ma-

ternal age and diabetic complications may carry an increased pregnancy risk.[9-11]

Previous studies on the frequency of infertility in diabetic women are few[1-4] and seem to comprise only selected patients. To our knowledge the current study is the first published survey on infertility and pregnancy outcome in an unselected population of diabetic women.

In a previous study[7] in which a similar patient identification method was used, the estimated completion of the study material was 98%. Our response rate of 94% in the diabetic population and 88% in the control population is higher than obtained in most other questionnaire studies on gynecologic topics.[5, 12, 13] Thus our methods concerning population identification and data sampling seem sufficient.

The definition of infertility is arbitrary. Some authors define infertility as failure to conceive after 2 years without contraception,[5, 13] whereas most demand only 1 year, and the proportion of couples to whom this applies is between 10% and 28%.[13-17] The infertility rate of 17% as observed by us in the control group is comparable to these results and probably represents the size of the infertility problem in the general population.

Our results show that the overall rate of involuntary infertility in diabetic women of 17% is virtually identical to that of controls. This finding seems surprising because menstrual disturbances in these women occur with a frequency twice that of the controls (Kjaer K, et al. Unpublished data). We have no explanation for these conflicting results. Recent studies in unselected diabetic populations are not available, but in selected diabetic patients an infertility rate of 21% has been reported from a pregnancy clinic.[4]

Diabetic women and controls also have the same cumulative rate of pregnancy, which suggests that the time to conceive is similar in the two groups. As also observed in other studies,[5, 13] most of our infertile diabetic women and infertile controls had primary infertility, and more than half of these women eventually became pregnant. There was no trend toward a lower frequency of pregnancies in infertile diabetic women compared with infertile controls. Infertile diabetic women were significantly younger than infertile controls, which may indicate that infertility as a clinical problem may occur at an earlier stage in diabetic women compared with nondiabetics.

Our investigation has shown that there was a trend toward more women being voluntarily infertile in the diabetic population than among controls. Further, voluntary infertility occurs with similar frequency in younger diabetics compared with controls but seems to be increased among older diabetic women. This finding may partly be attributed to the professional advice given by diabetologists and gynecologists who call for caution when diabetic women >30 years of age want to become pregnant. Another possibility is that the diabetic women >30 years have reached the age of re-

production at a time when physicians' attitudes toward diabetic pregnancy were considerably more negative than in recent years, and therefore these women may have been convinced of the inadvisability of pregnancy early in their reproductive years. The trend toward more diabetic women being voluntarily infertile may also be due to the observation that the presence of diabetes has a negative influence on their attitude toward having children.

It is generally accepted that poor metabolic control before and during the first weeks of pregnancy in diabetic women is associated with a substantial increased risk of spontaneous abortion and congenital defects. Such complications may be reduced to levels roughly equal to that of the general population if optimal metabolic control can be obtained.[18-22] Accordingly, modern diabetic care involves meticulous planning of pregnancies and the application of intensive metabolic monitoring and treatment to ensure the best possible blood glucose regulation in the individual patient. The present investigation has shown that 47% of all pregnancies in diabetic women in the period 1959 to 1989 was unplanned, and this value seems also to apply to the general population. Although the prevalence of unplanned pregnancies was highest in the first decade (1959 to 1969, 60%), when the importance of birth planning was not widely accepted, the rate of 43% during the last decade (1979 to 1989) is still unacceptably high. In the view of the authors this may raise serious doubts whether the therapeutic principles in diabetic women of fertile age are fully implemented in practice. Funen County has had a center for pregnant diabetic women with a diabetologist and an obstetrician since 1968; therefore this lack of planning may apply also to other centers in the Western world.

The 1.7 per woman rate of pregnancy in our control group is lower than that of 2.3 observed in a previous Danish study on 709 25- to 45-year-old women surveyed in 1979.[13] A deliberate choice to limit family size is probably responsible for most of the decline. Their induced abortion rate of 7% was somewhat lower compared with ours (12%). Because the former study was carried out about a decade before ours, this discrepancy is probably explained by the different access to legalized abortion (legalized in Denmark in 1973).

In diabetic women, the number of pregnancies is reduced compared with controls, in spite of the fact that the two groups were comparable with regard to involuntary infertility. As discussed previously, this observation is likely to be caused by the attitude on the part of both patient and therapist toward pregnancy in diabetic women. As expected, pregnancy outcome in diabetic women is characterized by fewer births per pregnancy compared with controls.

Our cesarean section rate of 45% among diabetic deliveries is comparable to that of 53% to 54% from other Danish centers.[23, 24] Although specific data on indication for cesarean section in our study groups are not obtainable, there is no doubt that the much higher rate in diabetic women is due to the increased perinatal risks in these patients.[25]

Because legalized abortion was introduced fairly early in Denmark compared with most other countries, meaningful comparisons of the rate of spontaneous or induced abortion are not possible. In our study spontaneous abortion was moderately increased in diabetics (15%) compared with controls (11%), which may indicate that optimal metabolic regulation before conception and during the first weeks of pregnancy had not been achieved. Another explanation could be the possibility of recall bias, with diabetic women being more aware of early spontaneous abortion than nondiabetic women because of their medical care. Our spontaneous abortion rate of 15% among diabetic women is comparable to that of 14% from Rigshospitalet, Denmark, from the years 1967 to 1986.[26]

In conclusion, fertility in diabetic women seems to be similar to that of the general population. Although optimal diabetic care can reduce the risks and complications of pregnancy and birth to normal levels, the majority of diabetic women still harbors a negative attitude toward having children because of their disease. This attitude seems to result in fewer pregnancies per diabetic woman and a higher proportion of diabetic women abstaining from having children compared with controls. Moreover, a medically unacceptable proportion of diabetic pregnancies is unplanned. There appears to be a need for intensifying the educational and therapeutic efforts in diabetic women of fertile age.

Effects of mefenamic acid on menstrual hemostasis in essential menorrhagia

Marion A. van Eijkeren, MD, PhD,[a] Godelieve C.M.L. Christiaens, MD, PhD,[a] Hans J. Geuze, MD, PhD,[b] Ary A. Haspels, MD, PhD,[a] and Jan J. Sixma, MD, PhD[c]

Utrecht, The Netherlands

Prostaglandin synthesis inhibitors decrease menstrual blood loss by 30% to 50% in patients with essential menorrhagia. To obtain insight into their mechanism of action, we measured menstrual blood loss in menorrhagic women, who were receiving mefenamic acid (500 mg, three times daily) (n = 6) or placebo (n = 5) in a double-blind way. In addition we studied the morphology of early menstrual hemostasis. The subjects' uteri were extirpated in the first 24 hours of menstruation, and light and electron microscopy were used to perform morphologic and morphometric studies. In the group treated with mefenamic acid mean menstrual blood loss was decreased by 40%. In uteri of the women treated with mefenamic acid hemostatic plugs were further transformed, and fewer vessels without a plug were observed than in uteri of the group receiving placebo. These data suggest that mefenamic acid may act through an improvement of platelet aggregation and degranulation and through increased vasoconstriction. (Am J Obstet Gynecol 1992;166:1419-28.)

Key words: Menorrhagia, mefenamic acid, endometrium, morphometry, hemostasis.

Prostaglandin synthesis inhibitors are currently the treatment of first choice in essential menorrhagia (i.e., a measured menstrual blood loss of more than 80 ml from a normal secretory endometrium after a normal ovulatory cycle). They inhibit cyclooxygenase, the enzyme that metabolizes arachidonic acid toward unstable endoperoxides. These endoperoxides are converted further toward prostaglandins. Prostaglandin synthesis inhibitors diminish menstrual blood loss by 30% to 50% and have a low incidence of side effects.[1, 2] Mefenamic acid is the best-studied prostaglandin synthesis inhibitor in essential menorrhagia.

In the endometrium of menorrhagic women, an increased fibrinolysis[3] and a shift in uterine prostaglandin metabolism towards vasodilating and platelet aggregation–inhibiting prostaglandins (prostaglandin E_2 and I_2) have been observed.[4-7] More binding sites for prostaglandin E_2 were also found in the myometrium of menorrhagic women.[8] Treatment of menorrhagic women with mefenamic acid decreased endometrial prostaglandin E_2 concentrations and myometrial prostaglandin E_2 binding sites.[9, 10]

Despite this knowledge, the mechanism of action of prostaglandin synthesis inhibitors in essential menorrhagia is not yet understood, though an effect on menstrual hemostasis is assumed.

It has been previously demonstrated that hemostasis in human skin wounds takes place through platelet adhesion to the subendothelium of damaged vessels followed by platelet aggregation and degranulation. Finally fibrin fibers are formed between the platelet remnants to preserve a stable, fully transformed, occlusive plug.[11] Hemostasis in menstrual endometrium was also studied, and differences were found compared with that in skin wounds. In the endometrium, damaged vessel walls often occurred without any hemostatic reaction, and the relatively small hemostatic plugs seldom occlude the vessel completely as they usually do in skin wounds. Only during the first 20 hours of menstruation were hemostatic plugs found. Thereafter hemostasis is probably provided by vasoconstriction.[12]

In a recent study[13] uteri of menstruating menorrhagic women were found to contain two forms of hemostatic plugs that had never before been observed in normally menstruating women.[12] First, huge fragile plugs with large protrusions into the extravascular space were observed. This condition was evidently the result of a decreased platelet aggregation and degranulation, which may reflect increased prostaglandin I_2 and E_2 concentrations or an unknown local anticoagulant. Second, otherwise well-transformed plugs often demonstrated extensive recanalization, which may reflect increased fibrinolysis. We also found that increased menstrual blood loss and, hence, essential menorrhagia

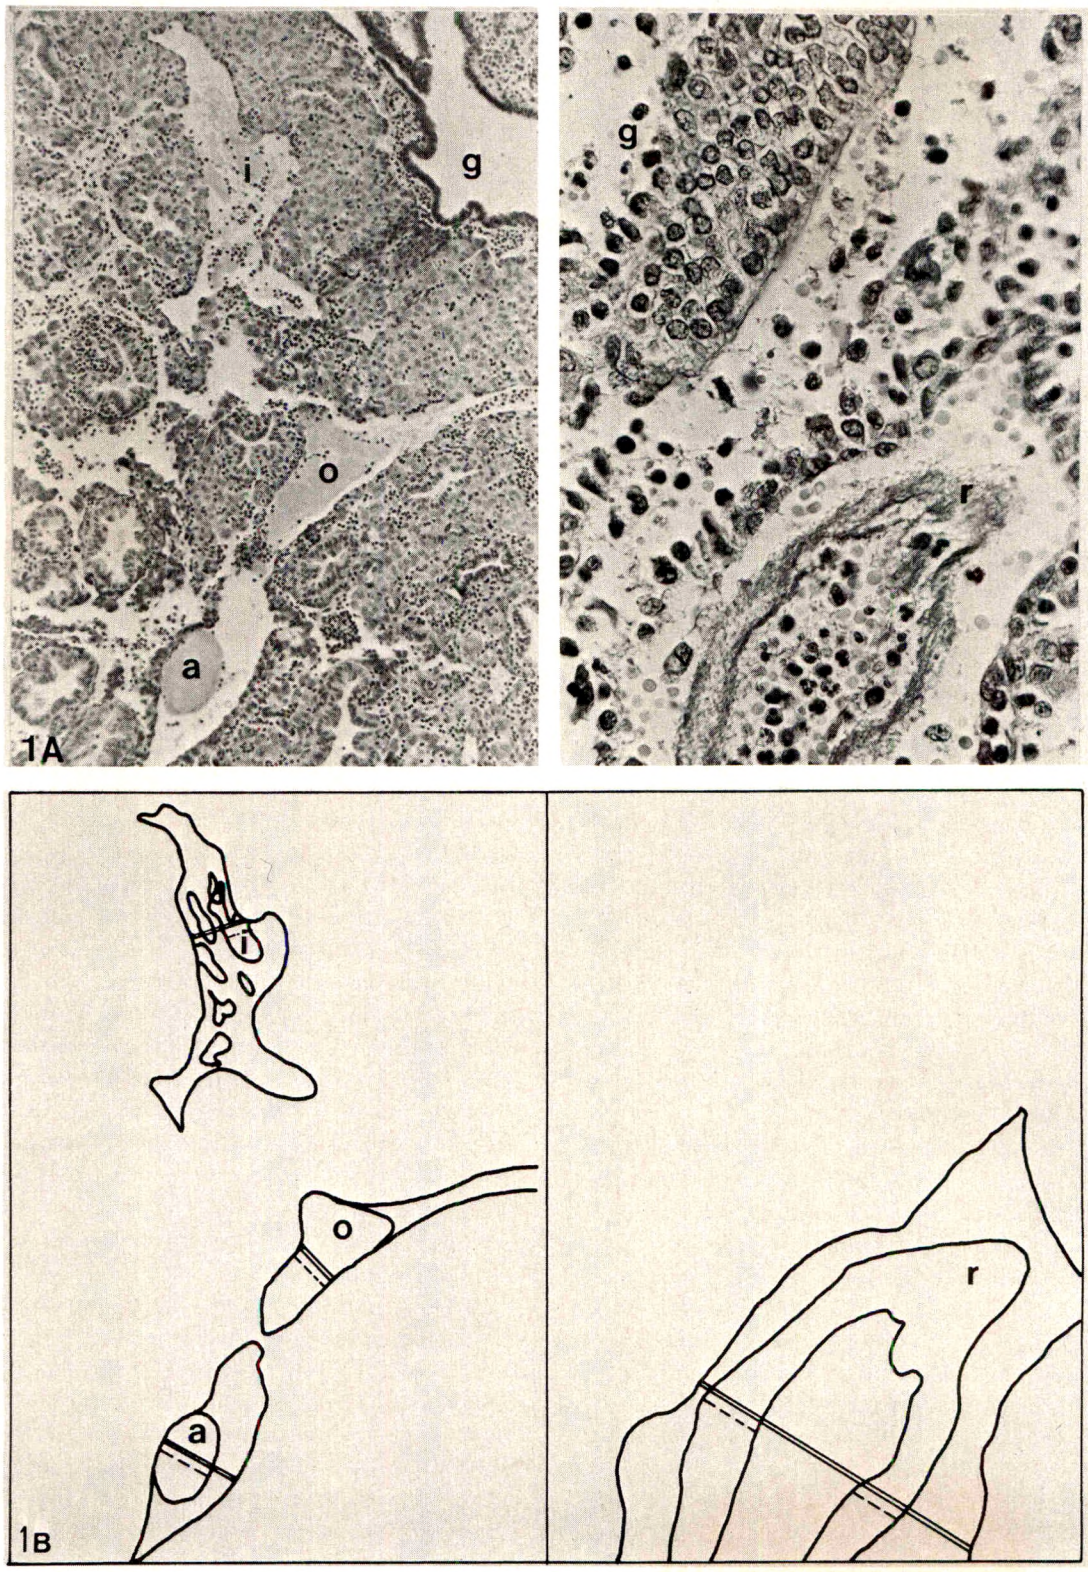

Fig. 1. Light micrographs (**1A,** *upper panels*) and corresponding line drawings (**1B,** *lower panels*) from paraffin sections stained according to Martius scarlet blue[13] showing various plug types and diameters measured. Diameters were measured at smallest width. *Solid* and *dotted lines* represent diameters of vessels and plugs. Relative occluded vessel diameter was calculated by dividing diameter of plug by diameter of vessel. *a,* Nonocclusive plug, smaller than occlusive, may be adherent to vessel wall (as pictured) or in middle of vessel (not pictured); *g,* gland; *i,* indifferent plugs (plugs not fitting other descriptions); *o,* occlusive plug, hemostatic plug occluding vessel; *r,* recanalized plug, peripheral platelet and fibrin deposition representing a former occlusive hemostatic plug that is recanalized. (Original magnification: *left,* ×90; *right,* ×358.)

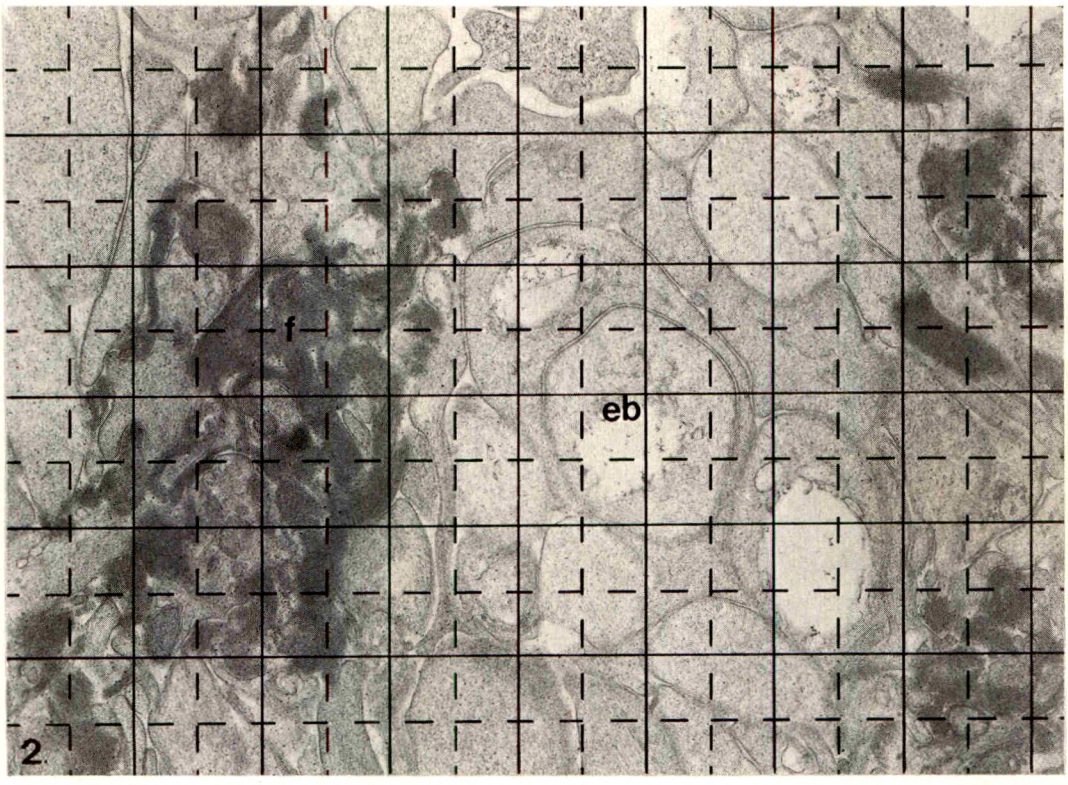

Fig. 2. Morphometric method used to assess volume fractions of empty balloons and fibrin fibers. Electron micrograph showing part of a hemostatic plug, mainly consisting of empty balloons *(eb)* and fibrin fibers *(f)*. *Solid* and *dotted lines* were used to measure volume fractions of empty balloons and fibrin fibers, respectively. We used the so-called point-hit method of counting line intersections overlying empty balloons and fibrin fibers. Numbers were expressed as percentages of total number of intersections counted. (Original magnification ×20,160.)

were positively correlated with the number of hemostatic plugs.

The present study was designed to investigate the effect of prostaglandin synthesis inhibitors on menstrual hemostasis in essential menorrhagia.

Material and methods

Patients scheduled for hysterectomy because of subjective menorrhagia were asked to participate in the trial and informed consent was obtained. Only women who met the following criteria entered the trial: younger than 45 years of age; measured menstrual blood loss more than 80 ml; regular menstrual cycle; no intrauterine device; no use of nonsteroidal antiinflammatory drugs or other medication that could interfere with hemostasis; no contraindications against the use of nonsteroidal antiinflammatory drugs, such as liver or kidney function impairment, stomach ulcers, or asthmatic bronchitis; and no use of hormonal medication. The women had normal-sized uteri as assessed by bimanual palpation.

The time schedule of the trial was as follows: menstrual blood loss was measured during one menstruation (control period) with the previously described alkaline hematin method.[14] If blood loss exceeded 80 ml, patients entered the trial. Five days before the expected next menstruation (study period) they started to use mefenamic acid (Ponstan) 500 mg or a placebo three times daily. Neither the patient nor the treating physician was aware of the nature of the administered drug. The sequence of placebo and tablets containing mefenamic acid was determined according to a random list kept at the Pharmacy of the University Hospital Utrecht. Patients continued to use tablets until menstrual bleeding had arrested. Menstrual blood loss was then measured again. Five days before the expected next menstruation, patients started to use the same tablets as during the study period. Vaginal or abdominal hysterectomy was performed in the patient under general anesthesia during the first 24 hours of menstruation. Basal body temperature charts were kept and progesterone levels were assessed with radioimmunoassay in the midluteal phase of the preoperative cycle and at the time of operation.[15] Plasma levels of mefenamic acid were assessed with a high-pressure liquid chromatographic method during the study period and at the time of operation.

The study was approved by the committee of research on human beings at the University Hospital Utrecht.

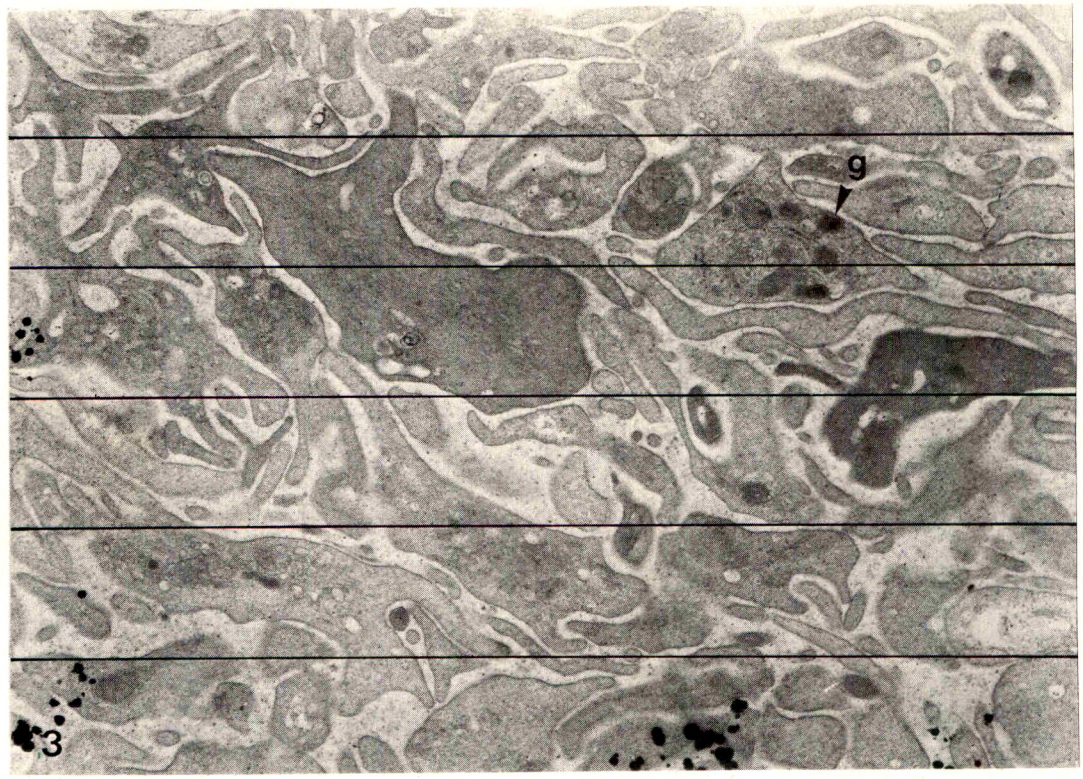

Fig. 3. Morphometric method used to assess platelet membrane surface area and granule numeric density. Electron micrograph showing part of hemostatic plug consisting of granulated and degranulated platelets. Numbers of intersections between platelet membranes and superimposed lines were counted according to linear intercept method. Platelet membrane surface area was calculated by dividing number of intersections times two by total length of superimposed line. Granules *(g)* were counted separately and granule numeric density was calculated by dividing number of granules by section thickness (70 nm). A calibration replica was used to correct for magnification. (Original magnification ×16,800.)

The placebo group was described as part of the study group in our previous study on menstrual hemostasis in essential menorrhagia.[13]

Tissue processing and morphometry. Tissue processing and morphometric methods using light and transmission electron microscopy were described in our previous study.[13] Morphometric analysis was performed on light microscopical sections with respect to endometrial height, number and diameter of endometrial vessels with or without a hemostatic plug, and size and form of hemostatic plugs. Four characteristic forms were distinguished: recanalized, occlusive, nonocclusive and indifferent (see Fig. 1). With electron microscopy, the transformation of the hemostatic plug was studied: volume fractions of fibrin and empty balloons (see Fig. 2) and membrane surface area and granule density (see Fig. 3) were calculated.[16] The extravascular extension of hemostatic plugs was also studied with electron microscopy. Morphometric parameters were expressed for each uterus. The double-blind codes were broken only after morphometric determinations had been finished.

Statistical analysis. Because not all variables were normally distributed, the Wilcoxon rank sum test was used to study differences between the two groups. The Spearman rank correlation coefficient was used to study correlations between the difference in menstrual blood loss of the mefenamic acid group (menstrual blood loss in the control cycle minus menstrual blood loss in the study cycle) and morphometric data.

Results

Patients. After 4 years and with the cooperation of many patients and gynecologists a sufficient number of uteri for our study were extirpated in the first 24 hours of menstruation.

Nineteen patients entered the trial. Seven patients dropped out from the trial after the study cycle or at the time of operation for the following reasons: Four patients postponed hysterectomy or wanted only a planned hysterectomy; one was found to have a large leiofibromatous uterus at operation; one was already in a postmenstrual phase at operation; and one was in a premenstrual phase at operation. The one discontin-

*$p = 0.01$. Other differences were not significant.

uation was in a patient who stopped medication because of severe skin rash and itching. Her tablets contained mefenamic acid.

Eventually 11 uteri were available for examination, six from women in the mefenamic acid group and five from the placebo group. Only a few side effects were reported spontaneously. In the placebo group one patient mentioned headache and another itching. In the mefenamic acid group one patient mentioned stomach pains and, apart from the patient who discontinued the trial because of itching, another patient also complained of itching. No additional side effects were mentioned when the patients were questioned.

Characteristics of the patients whose uteri were studied are shown in Table I. Progesterone levels measured at the midluteal phase and at the time of operation, together with the biphasic basal body temperature charts, indicate that preoperative cycles were ovulatory. Mefenamic acid levels during the treatment cycle and at operation show great variation but prove that all patients did take their tablets.

Menstrual blood loss. Data on menstrual blood loss are shown in Table II. Mean menstrual blood loss in the control period did not differ between both groups ($p = 0.09$). In the mefenamic acid group, all menstrual blood losses decreased during the study period and mean menstrual blood loss dropped by 40% ($p = 0.01$). All patients but one had menstrual blood loss in the normal range when treated with mefenamic acid. Mean menstrual blood loss in the control and the study period did not differ in the placebo group ($p = 0.46$).

Morphologic findings.

Morphometric data. Morphometric data are presented in Table III.

Aspect of the endometrium. Macroscopically, all 11 uteri had dark red, blood-engorged areas at hysterectomy. Microscopically, all uteri had endometria partly covered with epithelium, indicating that menstruation was still in an early phase at the time of hysterectomy. Endometrial height did not differ between the two groups, nor was endometrial height correlated with the interval between the onset of menstruation and the time of operation in the two groups.

Number of vessels with and without a plug. The total number of vessels seen in light microscopy, venules as well as arterioles, was significantly reduced in the mefenamic acid group compared with the placebo group ($p = 0.03$), which can be attributed to vessels without a plug ($p = 0.02$) because it is not true for vessels with a plug ($p = 0.60$). A possible explanation may be a

LM, Assessed in light microscopy; *EM*, assessed in electron microscopy. In light microscopy, all numeric data are expressed per 125 section fields (except for the endometrial height, which was expressed per 10 sections) at a magnification of ×25; in electron microscopy, per 10 to 15 ultrathin sections or 30 micrographs at ×7000 initial magnification.

*Significant p values (0.02 to 0.05).

†Data on arterioles and venules are given only if a statistically significant difference existed. In the placebo group, as well as in the mefenamic acid group, the ratio between venules and arterioles was 4:1.

more extensive vasoconstriction of vessels in the mefenamic acid group compared with that of the placebo group. Consequently, small constricted vessels will have escaped notice. Another possible explanation, a reduced vessel number in the mefenamic acid group, seems less probable, because mefenamic acid given 5 days before the expected menstruation is unlikely to reduce the number of vessels in secretory endometrium.

Menstrual blood loss in women in the placebo group correlated positively with the number of hemostatic plugs, both occlusive and nonocclusive, but not with other morphometric data.[13] This correlation was not seen in the mefenamic acid group.

Disruption of endothelium with and without a hemostatic plug was observed in the mefenamic acid and the placebo group to the same extent. Increased plugging of such vessel holes was thus not the explanation for the decreased blood loss in the mefenamic acid group.

Vessel diameter. There were no differences in the diameters of the total number of vessels between the mefenamic acid and placebo group. More specifically, this held true for venules but not for arterioles, which were significantly larger in diameter in the mefenamic acid group compared with the placebo group (p = 0.05). This difference between the total population of vessels and the population of arterioles can be understood if one realizes that in both groups more venules were counted than arterioles, with a ratio of 1:4 (see Table III). This finding of more diluted arterioles in the mefenamic acid group is in apparent contrast to the ob-

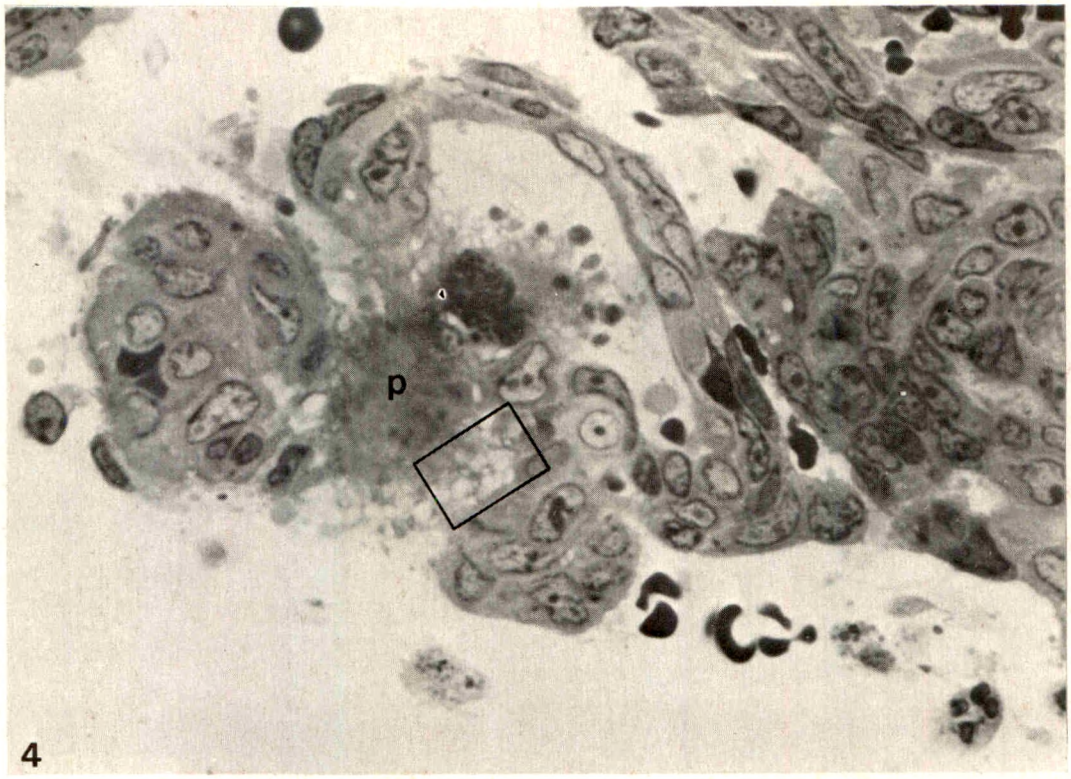

Fig. 4. Light micrograph of epon section showing small hemostatic plug *(p)*, with extravascular extension from patient receiving mefenamic acid. (Original magnification ×2163.)

servations above, where we concluded that vessels in the mefenamic acid group, venules as well as arterioles, probably were more contracted compared with the placebo group. This difference can be understood if one assumes that because of the greater amount of contracting cells in their vessel wall small arterioles are more often contracted than small venules and hence less noticed. Consequently the arterioles in the mefenamic acid group will be fewer and larger.

Size of plugs. Plugs in both groups varied in size from small to huge and loose ones. In the mefenamic acid group, fewer huge plugs were observed than in the placebo group. Plugs extending into the extravascular space were observed in both groups (see Figs. 4 and 5), but the extravascular extensions were smaller in the mefenamic acid group. This difference could not be confirmed with electron microscopic morphometric analysis (see Table III), probably because of the limited number of cross sections available. The area occluded by hemostatic plugs in venules and small arterioles was greater in the mefenamic acid group than in the placebo group ($p = 0.05$).

Form of plugs. All four characteristic plug types, recanalized, occlusive, nonocclusive, and indifferent, were observed in both groups. Recanalized plugs were observed significantly more often in arterioles of the mefenamic acid group ($p = 0.05$). However, this observation is of limited value inasmuch as the total number of recanalized plugs in arterioles is small (seven in the placebo group and nine in the mefenamic acid group). There were no significant differences in other forms of hemostatic plugs. As described earlier,[13] menstrual blood loss in the placebo group was positively correlated with the number of both occlusive and nonocclusive plugs.

Transformation of the plug. Direct observation showed that plugs of women treated with mefenamic acid seemed further transformed than those of women treated with placebo; platelets were more firmly interdigitated and more degranulated and more empty balloons and fibrin fibers were noticed (see Figs. 6 and 7). The transformation of the hemostatic plugs was also studied morphometrically at the electron microscopic level. Good correlation was observed between the decrease in menstrual blood loss during use of mefenamic acid and combined parameters of further transformation of the plug ($p < 0.025$).

Comment

The reduction of menstrual blood loss by prostaglandin synthesis inhibitors is well known but poorly understood. In this study, we describe the effect of one

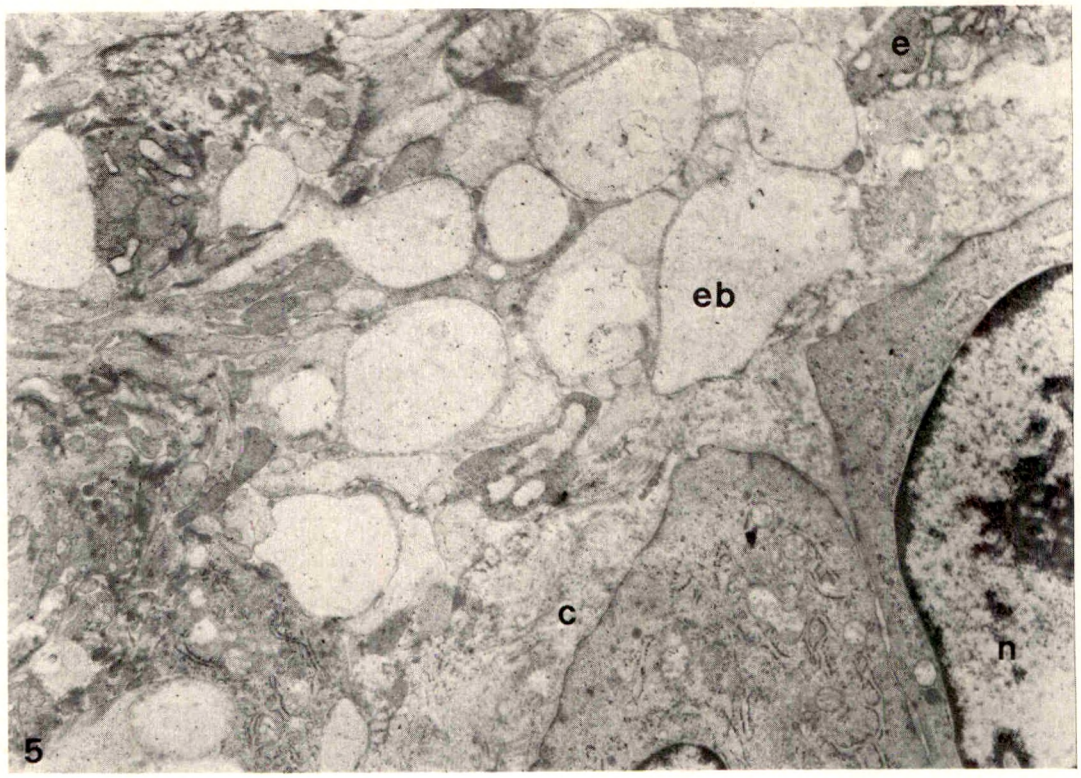

Fig. 5. Electron micrograph of area in *box* in Fig. 4 showing disrupted endothelium *(e)*. Empty balloons *(eb)* are attached to subendothelial collagen *(c)*. *n*, Nucleus of subendothelial cell. (Original magnification ×11,880.)

widely used inhibitor, mefenamic acid, on menstrual blood loss and on the morphologic features of early menstrual hemostasis in menorrhagic women. Mefenamic acid and placebo were used in a double blind study. Mefenamic acid decreased menstrual blood loss by 40%, which is in accordance with previous reports.[1, 2]

The morphologic features of early menstrual hemostasis of both groups were strikingly different. In the mefenamic acid group, fewer huge hemostatic plugs were observed and their extravascular extensions were smaller. Hemostatic plugs in the mefenamic acid group were further transformed than those in the placebo group. Three other significant differences of interest were found in the morphometric studies. First, the number of vessels without a hemostatic plug was decreased in the mefenamic acid group. Second, the vessel area occluded by a plug in venules was increased in the mefenamic acid group. Third, the degree of hemostatic plug transformation correlated inversely with the decrease in menstrual blood loss in the mefenamic acid group.

The differences described here suggest that mefenamic acid may act through vasoconstriction and improvement of platelet aggregation and degranulation. These changes obviously decrease the amount of menstrual blood loss.

The observed changes may have been mediated by inhibition of prostaglandin I_2 and E_2 synthesis. An effect of mefenamic acid or other nonsteroidal antiinflammatory drugs on fibrinolysis has never been described. Recanalization of plugs, reflecting increased fibrinolysis, was seen as frequently in the venules of the placebo group as in the mefenamic acid group. In arterioles, recanalized plugs were seen significantly more often in the mefenamic acid group, but this is of little value because of their small number.

The effect of mefenamic acid on menstrual hemostasis in essential menorrhagia is strikingly different from the effect of acetylsalicylic acid in human skin wounds.[17] Acetylsalicylic acid caused impairment of platelet aggregation and degranulation. The discrepancy may be the result of a different prostaglandin metabolism in the human skin compared with menstrual endometrium of menorrhagic women, or by a different mode of action between acetylsalicylic acid and mefenamic acid. The fact that acetylsalicylic acid does not decrease menstrual blood loss[18] is an argument for the latter hypothesis.

How precisely mefenamic acid causes vasoconstriction and further transformation of hemostatic plugs remains to be answered. Granström et al.[19] have suggested that under the influence of prostaglandin synthesis inhibitors on cyclooxygenase, arachidonic acid is predominantly metabolized toward leukotrienes via the lipoxygenase pathway. Leukotrienes are strong vaso-

constrictors and would reduce menstrual blood loss. Our findings are in agreement with such a hypothesis. Additionally, we also found an improvement of the transformation of the hemostatic plug in menstrual endometrium of women receiving mefenamic acid. How this is related to prostaglandin metabolism in endothelial cells and platelets deserves further study.

We thank the staff members and residents of the Departments of Obstetrics and Gynecology and Anesthesiology of the University Hospital of Utrecht and to the gynecologists J.W. Briet, Prof. T.K.A.B. Eskes, J. Koudstaal, R. Kriek, J.M.W.M. Merkus, H.A.L.M. Mudde, H.J.M. Roelofs, W. Vlaanderen, and M.A.H.M. Wiegerinck for their cooperation in performing hysterectomies at any time of night or day. Elevated plasma Met-enkephalin levels in the human newborn are a poor indicator of perinatal stress

Alma M. Martinez, MD,[a, b] James F. Padbury, MD,[b] Leslie M. Barberie, BS,[b] Elizabeth E. Burnell, BS,[b] and Siang Thio, BS[b]

Los Angeles and Torrance, California

OBJECTIVE: This study was designed to investigate whether plasma Met-enkephalin peptides could serve as markers of physiologic stress in the neonate.

STUDY DESIGN: Infants (n = 115) between 1.2 and 4.7 kg and 28 and 42 weeks of gestation were studied at birth. Seventy-four infants were delivered by the vaginal route, 31 by cesarean section after labor, and 10 by cesarean section before labor. Correlations were sought between plasma enkephalin peptides and epinephrine, norepinephrine, and arterial blood gases with linear regression analysis. Various clinical data were also analyzed.

RESULTS: Plasma Met-enkephalin levels were significantly greater in infants exposed to labor (440 ± 36 vs 260 ± 30 pg/ml, $p < 0.05$). The large-molecular-weight forms of enkephalin peptides were also greater in these infants (approximately 50 ± 4 vs 23 ± 2 ng/ml). There was no correlation between plasma enkephalin peptides and catecholamines, arterial pH, or Apgar scores. There was a significant but weak correlation between plasma Met-enkephalin levels and birth weight ($r = 0.34$, $p = 0.03$) and Pao_2 ($r = -0.28$, $p < 0.05$).

CONCLUSION: The lack of correlation between Met-enkephalin plasma levels and umbilical plasma catecholamine concentrations, acid-base status, or Apgar scores suggests that circulating Met-enkephalin is a poor indicator of stress in the newborn. (Am J Obstet Gynecol 1992;166:1429-35.)

Key words: Met-enkephalin, catecholamines, umbilical cord blood

The enkephalin peptides are a family of related peptides that include Met-enkephalin, Leu-enkephalin, larger-molecular-weight carboxy-extended forms of Met-enkephalin, and the prohormone proenkephalin A.[1] Investigators have shown cosecretion of discrete forms of the enkephalin peptides with catecholamines into the circulation in response to diverse stimuli.[2-4] We have previously shown plasma Met-enkephalin levels are elevated in a group of healthy newborn infants at the time of birth when compared with adult volunteers.[5]

Numerous investigators have reported elevated levels of plasma catecholamines at birth.[6, 7] In addition, we demonstrated by multiple regression analysis that among a variety of clinical variables umbilical arterial plasma catecholamines correlated best with the degree of acidemia in umbilical cord blood at delivery.[7] The current study was designed to investigate whether measurement of plasma enkephalin peptides could be used as a marker of physiologic stress in the neonate. We sought to find correlations between enkephalin peptides with characteristics of labor, route of delivery, arterial blood gases, and plasma catecholamines. In addition, we evaluated correlations between circulating plasma enkephalin peptides and clinical characteristics of newborn infants.

Material and methods

Study protocol. Institutional review board approval was obtained to collect umbilical cord blood from infants born at Harbor–University of California, Los Angeles Medical Center. Blood was drawn from the placenta immediately after cord clamping for measurement of plasma Met-enkephalin, larger-molecular-weight Met-enkephalin-containing peptides, plasma catecholamines, and arterial blood gas analysis. Clinical data were obtained from the mothers' and infants' medical records and included presence and duration of labor, Apgar scores, fetal heart tracing, birth weight, gestational age, and route of delivery.

Laboratory analysis. Blood for measurement of Met-enkephalin was immediately placed into chilled test tubes containing sodium citrate (0.5 mmol/L, final concentration), aprotinin (500 U/ml), and ethylenedi-

aminetetraacetic acid (3 mmol/L). Arterial blood for measurement of catecholamines was immediately placed into chilled tubes containing reduced glutathione (3 mmol/L) and ethylene glycol-bis(β-aminoethyl ether)N,N,N′,N′-tetraacetic acid (4 mmol/L). All samples were centrifuged, and the plasma was separated and frozen at −70° C for analysis.

Plasma for Met-enkephalin analysis was first extracted with polystyrene columns and then measured by radioimmunoassay as previously described.[8] Because the antiserum used cross reacts 2.8% with Leu-enkephalin, the data represent Met-enkephalin immunoreactivity. Plasma measurement of the Met-enkephalin immunoreactivity released from the high-molec-

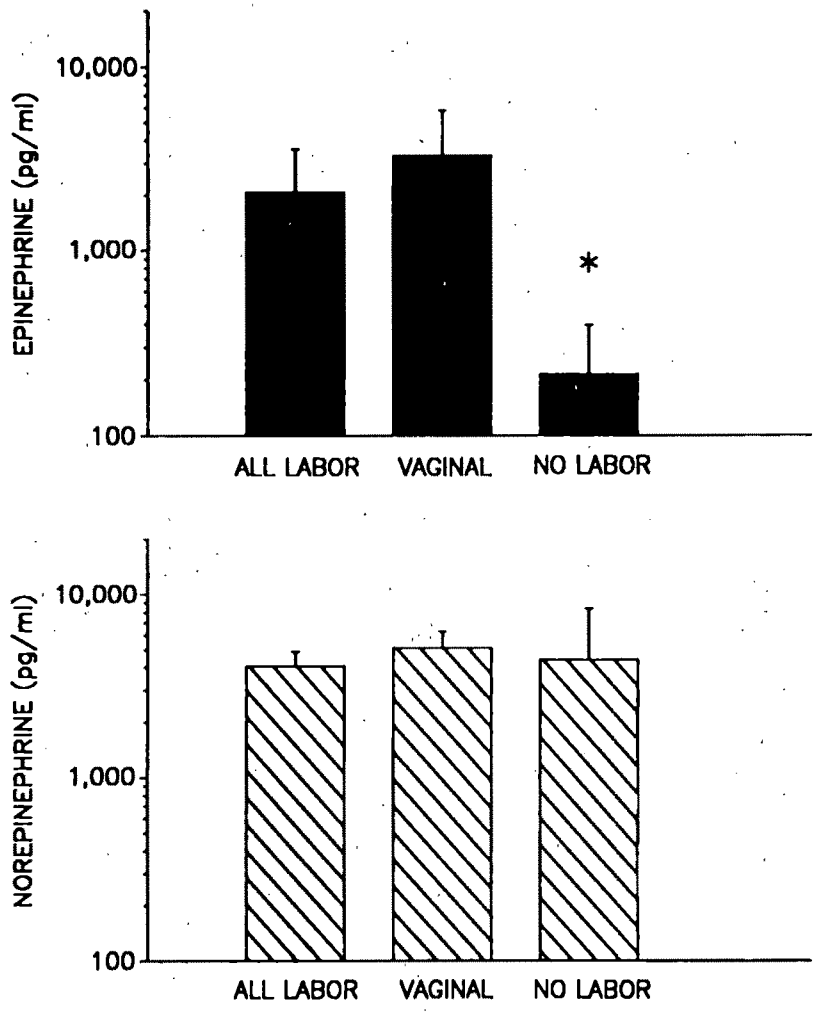

Fig. 2. Umbilical cord plasma epinephrine *(upper panel)* and norepinephrine *(lower panel)*. *Asterisk*, $p < 0.05$ (Mann-Whitney).

ular-weight enkephalin peptides first underwent proteolytic digestion with trypsin and carboxypeptidase B, as previously described.[2,8] The plasma was extracted and measured by radioimmunoassay as described above. The assay is sensitive to 2 pg. The interassay and intraassay variabilities were 13% and 9%, respectively. Recovery of Met-enkephalin with this assay was determined to be >90% after 1000, 500, or 200 pg/ml additions to unextracted plasma.

Plasma catecholamines were measured by a radioenzymatic assay sensitive to 1 to 2 pg of norepinephrine and epinephrine, as previously described.[9]

Data analysis. The data are presented as mean and SEM. The catecholamine data were log transformed for statistical analysis. The Mann-Whitney nonparametric test was used for comparisons between the different groups studied. Linear regression and stepwise multiple regression analysis was used to compare the enkephalin levels with clinical parameters and hormonal measurements. A value of $p < 0.05$ was considered statistically significant.

Results

One hundred fifteen infants were studied. Seventy-four were born by vaginal route and 31 by cesarean section after a trial of labor and 10 without any exposure to labor. In Table I the infants are divided into infants exposed to labor (group 1), infants delivered vaginally (group 2), and infants delivered by cesarean section without labor (group 3). The birth weights of the infants ranged from 1.2 to 4.7 kg, and the gestational ages ranged from 28 to 42 weeks. Table I also shows additional information obtained from the maternal records, including birth weight, gestational age, arterial pH and PaO_2, and Apgar score. As can be seen from the range of values, this was a diverse group of infants, some of whom were quite ill at the time of delivery.

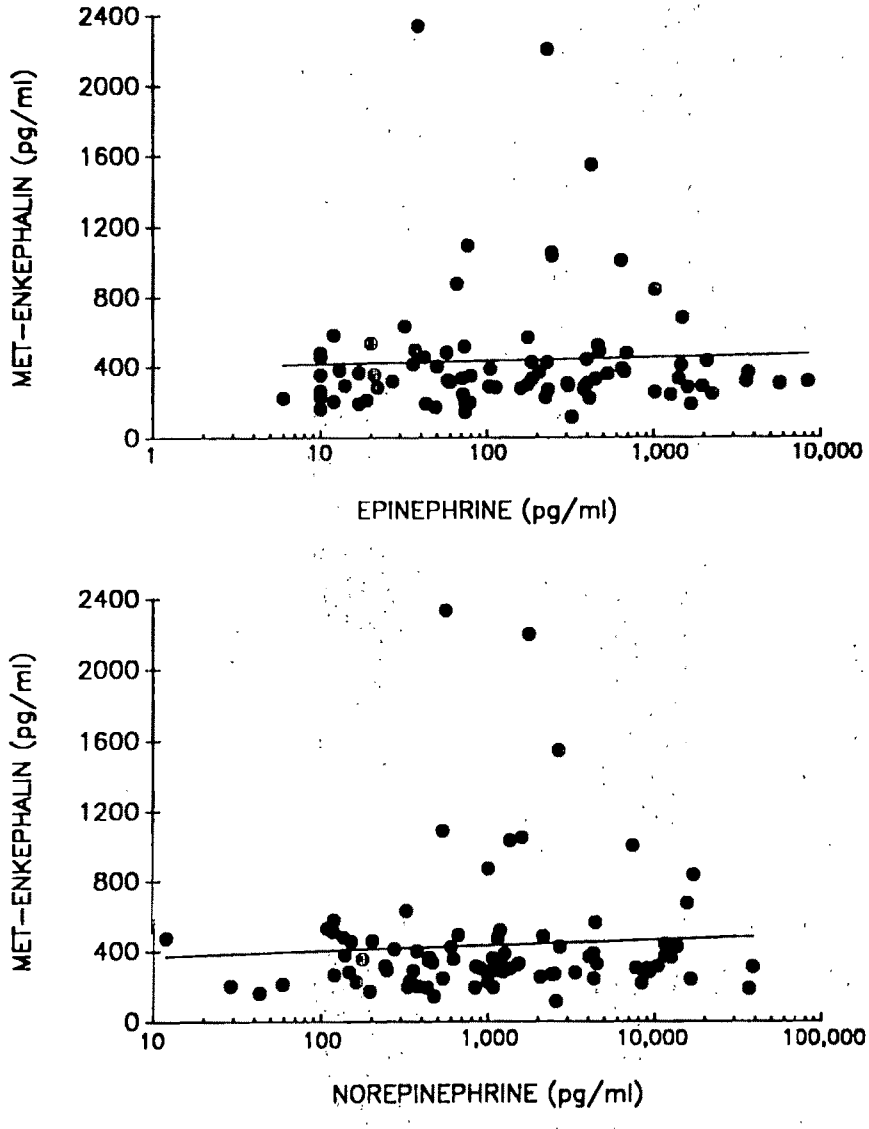

Fig. 3. Linear regressions between Met-enkephalin immunoreactivity and plasma epinephrine *(upper panel)* and norepinephrine *(lower panel)* in 87 paired samples.

The plasma enkephalin peptide levels are shown in Fig. 1. Plasma Met-enkephalin immunoreactivity levels were significantly greater in those infants undergoing labor before delivery, with levels of 450 ± 40 pg/ml for all labor and 400 ± 30 pg/ml for vaginal delivery versus 260 ± 30 pg/ml for patients delivered with no labor. Similarly, the high-molecular-weight enkephalin peptide levels were higher in infants born after labor when compared with infants born with no exposure to labor, with levels of approximately 50 ± 4 versus 23 ± 2 ng/ml.

As can be seen in Fig. 2, plasma epinephrine levels were similarly elevated in infants born after labor, with levels of 3300 ± 2400 and 4000 ± 3000 pg/ml versus levels of 300 ± 250 pg/ml in those infants born by cesarean section with no labor. There were no differences in plasma norepinephrine levels among the three groups of infants.

With linear regression in 87 paired samples we could find no correlation between high-molecular-weight enkephalin peptide and plasma epinephrine ($r = -0.102$, $p = 0.35$) or norepinephrine ($r = -0.06$, $p = 0.6$). These data are shown graphically in Fig. 3. Although not shown, there was similarly no correlation between high-molecular-weight enkephalin peptide versus epinephrine or norepinephrine. Using stepwise multiple regression analysis we found weak but significant correlations between Met-enkephalin immunoreactivity and birth weight and Pao_2 ($p < 0.05$). A second-order equation best fit the data and is shown in Fig. 4.

Comment

This study was undertaken to determine whether measurement of plasma Met-enkephalin or enkephalin-related peptides could be used as markers of phys-

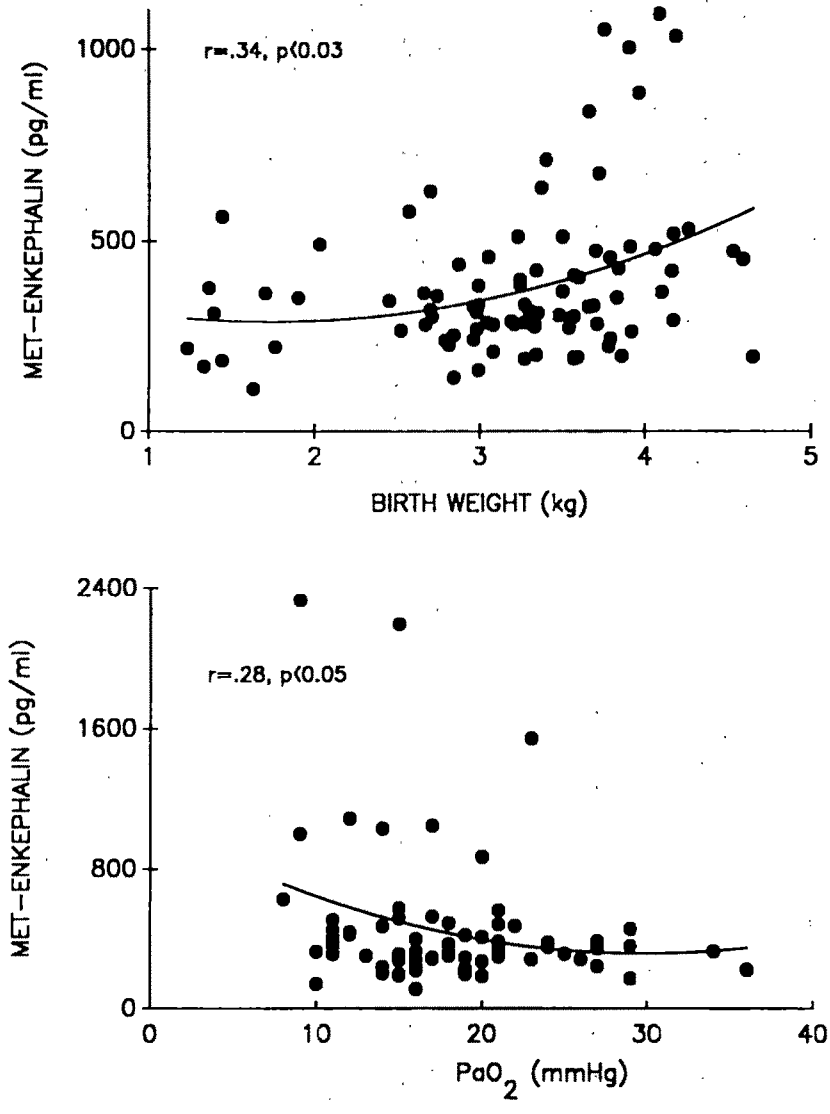

Fig. 4. Linear regressions between Met-enkephalin immunoreactivity and birth weight *(upper panel)* and PaO_2 *(lower panel)* in 87 paired samples.

iologic stress in the newborn at birth. We asked whether circulating enkephalin peptides would correlate with established markers of perinatal stress, such as arterial blood gases and plasma catecholamines. In addition, we sought to find significant correlations between circulating enkephalin peptides and clinical characteristics of newborn infants, such as gestational age, birth weight, Apgar scores, and mode of delivery. We had previously reported plasma high-molecular-weight enkephalin peptide levels to be significantly greater in a smaller group of healthy newborn infants' umbilical cord blood when compared with that of nonpregnant adult volunteers, whose plasma levels were approximately 25 ± 2 pg/ml. The plasma high-molecular-weight enkephalin peptide levels were not elevated in these newborn infants when compared with adult levels.[5]

In the current study we found that plasma Met-enkephalin immunoreactivity and high-molecular-weight enkephalin peptide levels were significantly greater in infants born after a trial of labor. We similarly found plasma epinephrine levels to be greater in these same infants. In addition, we found significant but weak correlations between plasma Met-enkephalin immunoreactivity versus birth weight and arterial PaO_2. We found no correlation between plasma levels of Met-enkephalin immunoreactivity or high-molecular-weight enkephalin peptide versus plasma epinephrine or norepinephrine, systemic pH, or Apgar scores.

The opiate peptides (which include enkephalins, endorphins, and dynorphins) have been implicated in the response to diverse forms of stress, including hypoxia, hypoglycemia, hemorrhage, and septic shock.[8, 10, 11] The opiate peptides and their receptors have been identified in central nervous system areas important for autonomic, cardiovascular, and respiratory control.[10] Recent

investigations have suggested the opiate peptides may play a role in the response to asphyxia and hypoxia in the fetal and neonatal period.[15] β-Endorphin is elevated during pregnancy, in response to labor and delivery.[16] An inverse correlation between β-endorphin and umbilical cord PaO_2 and pH have been previously shown in both sheep and human studies.[15, 16] β-Endorphins have also been shown to be elevated in term and premature infants born with perinatal depression.[17] By contrast, the role of the enkephalin peptides during delivery and perinatal stress has not been fully examined.

The physiologic role of opiate peptides has been the subject of many investigations. In vitro studies have shown that opiate peptides inhibit norepinephrine release in sympathetic ganglia through presynaptic inhibition of cholinergic transmission.[18] Opiate peptides have also been shown to inhibit adrenal catecholamine release in response to cholinergic stimulation.[19] In vivo studies with the opiate receptor antagonist, naloxone, have shown increases in circulating catecholamines and improvements in blood pressure and circulatory function in different animal models of shock.[10, 11, 20] We have shown that opiate peptide receptor blockade with naloxone augments epinephrine levels in fetal sheep exposed to hypoxia[21] and augments catecholamine levels and cardiovascular responses in newborn sheep at birth.[22]

The enkephalins are localized in brain stem nuclei involved in autonomic regulation, in sympathetic neurons and sympathetic ganglia, and in chromaffin cells of the adrenal medulla.[23, 24] In the adrenal medulla the enkephalin peptides are costored with catecholamines as Met-enkephalin and Leu-enkephalin and as larger-molecular-weight peptides, including the prohormone proenkephalin A.[1] All forms of enkephalin peptides have been shown to be coreleased with catecholamines from the adrenal gland during physiologic stimuli.[2] In this current study we found concomitant elevations of plasma Met-enkephalin peptides and catecholamines at birth. In addition, the highest levels of enkephalin peptides and epinephrine are found in those infants exposed to labor. These data do not negate or prove that cosecretion of these peptides occurs at birth. Differences in the secretion rates or plasma clearance rates of these peptides in the newborn may account for the lack of correlation seen in the circulating levels. These unresolved questions would represent exciting directions for future studies.

The increase in plasma Met-enkephalin seen in the perinatal period is consistent with the postulated role the opiate peptides have in the ventilatory and cardiovascular responses in the perinatal period.[12-14, 25, 26] The lack of correlation between Met-enkephalin plasma levels with catecholamines or systemic pH and the poor correlation with arterial PaO_2 suggests circulating Met-enkephalin is a poor marker of stress in the perinatal period. Furthermore, because proenkephalin A is only expressed in neural tissue (sympathetic neurons, ganglia, adrenal medulla, and the central nervous system), we speculate that the correlation seen in this study with birth weight may represent a neuromaturational phenomenon.

We thank the Perinatal Research Staff of the Clinical Research Center at Harbor–University of California, Los Angeles Medical Center, including Christine Mori, RN, Sara Alvarez, RN, and Artemesa McCullough, RN, for their assistance.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Lack of reactivity of uterine arteries from patients with obstetric hemorrhage

Sharon H. Nelson, PhD, and Maya S. Suresh, MD
Galveston, Texas

Obstetric hemorrhage may occur throughout pregnancy and the puerperium. The purpose of this study was to investigate the reactivity of isolated, suffused uterine arteries from obstetric patients with uncontrollable uterine bleeding and to compare those blood vessels with uterine arteries from patients undergoing cesarean hysterectomy for other medical reasons (control patients). The uterine arteries from the control patients (n = 9) responded with maximal or near-maximal constriction to norepinephrine (30 μmol/L, 3.6 ± 1 gm), potassium chloride (75 mmol/L, 10.2 ± 3 gm), prostaglandin $F_{2\alpha}$ (30 μmol/L, 1.8 ± 1 gm), and arginine vasopressin (1 μmol/L, 18.8 ± 2.6 gm). In uterine arteries from five patients with uncontrollable bleeding, the constrictor responses to the same drugs were markedly depressed: norepinephrine (30 μmol/L, 0.5 ± 0.2 gm), potassium chloride (75 mmol/L, 1.9 ± 0.8 gm); prostaglandin $F_{2\alpha}$ (30 μmol/L, 0 gm), and arginine vasopressin (1 μmol/L, 0.2 ± 0.05 gm). Uterine arteries from two patients exhibited no constrictor responses to norepinephrine (30 μmol/L), potassium chloride (75 mmol/L), prostaglandin $F_{2\alpha}$ (30 μmol/L), or arginine vasopressin (1 μmol/L). The impaired responses to the vasoconstrictor drugs were not reversed by indomethacin (1 μmol/L), which is an inhibitor of prostaglandin synthetase; methylene blue (10 μmol/L), which is a blocker of endothelium-derived relaxing factor activation of guanylate cyclase; or propranolol (1 μmol/L), a β-adrenergic receptor antagonist. The levels of adenosine 3′:5′-cyclic monophosphate were not elevated in the uterine arteries from the patients with obstetric hemorrhage. The impaired reactivity to the multiple vasoconstrictors implies that a mechanism involved in constriction common to all of the constrictors is depressed or blocked. Furthermore, the depression or lack of reactivity of these isolated uterine arteries is not mediated by vasodilatory prostaglandins, endothelium-derived relaxing factor, β-adrenergic receptors, or elevated levels of adenosine 3′:5′-cyclic monophosphate. The results suggest that obstetric hemorrhage involves, in part, a lack of constrictor reactivity of the uterine vasculature. (Am J Obstet Gynecol 1992;166:1436-43.)

Key words: Vascular smooth muscle, norepinephrine-induced constriction, potassium chloride–induced constriction, obstetric hemorrhage, pregnancy

Obstetric hemorrhage may occur throughout pregnancy and the puerperium. Postpartum hemostasis is generally thought to result from uterine muscle contraction and retraction and from thrombosis and fibrosis. Causes of the loss of this hemostasis, which results in uncontrollable uterine bleeding, include uterine atony, trauma to the genital tract and adjacent structures during labor and delivery, retained products of conception, coagulation defects, and abnormal placentation.[1] The management in cases of hemorrhage includes obstetric and pharmacologic maneuvers such as uterine massage, exploration and curettage of the uterus, surgical repair of traumatized tissue, and administration of ergots, oxytocin, prostaglandins, and other pressor drugs, as well as the administration of electrolytes, blood, and blood components.[1] If these measures are unsuccessful, emergency hysterectomy may be required.

Although a number of factors are associated with obstetric hemorrhage, virtually nothing is known about the reactivity of the uterine vasculature during uncontrollable uterine bleeding of pregnant patients. Uncomplicated (normal) pregnancy has been shown to have little or no effect on the responses of the human uterine artery to various constrictor agents.[2, 3] The possibility exists that the uterine vasculature of pregnant patients with uncontrollable uterine bleeding is depressed and thus does not constrict sufficiently for hemostasis. The purpose of this study was to investigate the reactivity of uterine arteries from patients with obstetric hemorrhage who underwent cesarean hysterectomy and to compare those blood vessels with uterine arteries from patients who underwent cesarean hysterectomy for other medical reasons (control patients). The use of uterine arteries obtained exclusively from pregnant patients avoided confounding hemodynamic, humoral,

and neurogenic influences of the nonpregnant condition.

A number of mechanisms responsible for the uterine vasodilatation that occurs during normal pregnancy have been investigated. For example, studies have shown that pregnancy increases the release from the endothelium of vasodilator substances such as endothelium-derived relaxing factor in the uterine artery from humans[4] and guinea pigs[5] or prostacyclin in the uterine artery from sheep.[6] Other studies suggest an alteration in calcium channels or intracellular calcium stores in the isolated uterine artery from the pregnant human.[2] Drug-induced increases in levels of adenosine 3′:5′-cyclic monophosphate (cAMP) are associated with relaxation of smooth muscle, and elevated basal levels of cAMP have been reported in uterine arteries from pregnant ewes.[7] Any of these mechanisms involved in decreasing uterine vascular tone during normal pregnancy may play an even greater role in uterine arteries from patients with obstetric hemorrhage.

Material and methods

Specimens of the ascending branch of the uterine artery were obtained from patients undergoing cesarean hysterectomy for various medical reasons. Use of the uterine arteries from patients undergoing hysterectomy was approved by the Institutional Review Board for the University of Texas Medical Branch, Galveston, Tex. Patients varied in age from 23 to 37 years. All gestations were term. The patients received antacid (Bicitra, Willen Drug Co.) for aspiration prophylaxis. Anesthesia was induced with thiopental and maintained with nitrous oxide–oxygen and either halothane, enflurane, or isoflurane.

Sections of the uterus that contained the uterine arteries were placed in gassed (95% oxygen and 5% carbon dioxide) Krebs-bicarbonate solution immediately after hysterectomy and before being taken to the laboratory. The preparation of isolated arterial rings and the suffusion techniques used have been described in detail previously.[8,9] In brief, rings 2 mm in length were prepared from the uterine artery and mounted between two tungsten wires in a 5 ml volume suffusion chamber. The diameter, measured by a dissecting microscope, of the unstimulated uterine artery taken from patients with uncomplicated pregnancy is not significantly different when compared with the uterine artery from multiparous, nonpregnant patients. Changes in isometric tension were measured by means of a force-displacement transducer (Statham) connected to the upper mounting wire and recorded on a Gould recorder (model 2400, Brush).

The mounted arteries were suffused continuously with gassed (95% oxygen and 5% carbon dioxide) Krebs-bicarbonate solution at a flow rate of 4 ml/min delivered by a peristaltic pump (Gilson Instruments). The Krebs-bicarbonate solution had the following composition: sodium chloride, 119 mmol/L; sodium bicarbonate, 25 mmol/L; potassium chloride, 3.6 mmol/L; magnesium sulfate, 1.2 mmol/L; potassium phosphate monobasic, 1.2 mmol/L; calcium chloride, 2.5 mmol/L; glucose, 11 mmol/L; ascorbic acid, 0.005 mmol/L; and disodium ethylenediaminetetraacetate, 0.03 mmol/L. The bath solution was maintained at 37° C and had a pH of 7.4. The drugs were adminstered in the inflowing suffusion fluid.

The preparation was allowed a stabilization period of 1 to 2 hours before the experiment began. During that time, basal tension was adjusted repeatedly until the resting tension became stable at 1 gm, which we have found to be the optimal resting tension for the human uterine arteries. Uterine arteries from patients having cesarean hysterectomy for medical reasons other than obstetric hemorrhage (control patients, type I) had reproducible constrictor responses to norepinephrine for several hours after the stabilization period.

The drugs studied, including norepinephrine, serotonin, arginine vasopressin, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and potassium chloride have multiple mechanisms of constriction, such as activation of receptor-operated and voltage-dependent calcium channels, as well as release of intracellular calcium. The concentrations of the drugs used in the studies were found to elicit 60% to 100% of the maximum constriction produced by each drug in uterine arteries from normal pregnant and nonpregnant patients. If little or no constriction was elicited by the vasoconstrictor drug, the drug concentration was increased. Each concentration of the constrictor drug was administered for at least 15 minutes, a time found to produce a stable constriction in uterine arteries from normal pregnant patients.[2] Each drug was washed out for 30 minutes before the subsequent administration of another drug.

The mechanisms for the impaired constrictor responses were investigated with the following procedure. Norepinephrine (30 μmol/L) was administered for 15 minutes. After the norepinephrine-induced constriction returned to baseline or after 15 minutes, the arterial ring was suffused for 30 minutes with a given concentration of indomethacin, to inhibit prostaglandin synthetase, with methylene blue, to prevent the effect of endothelium-derived relaxing factor on soluble guanylate cyclase, or with propranolol, to antagonize β-adrenergic receptors. Norepinephrine, in the presence of the antagonist or blocker, was again administered for 15 minutes.

To determine whether the impaired constrictor responses were due to elevated basal levels of cAMP that are associated with smooth muscle relaxation, basal

Table I. Categories of patients on basis of reactivity of isolated uterine arteries

Patient No.	*Lowest MAP (mm Hg)*	*Diagnosis*	*Estimated blood loss (ml)*	*Coagulopathy*	*Drugs*	*Associated clinical phenomena*
Type I (normal reactivity)						
03	84	Placenta accreta	–	–	—	Repeat cesarean section
04	83	Fibroids	–	–	—	—
65	80	Cervical carcinoma, marginal placenta previa	–	–	Levothyroxine sodium (Synthroid)	Amniocentesis
74	85	Cervical cancer	–	–	—	Amniocentesis
72	97	Severe dysplasia	–	–	—	Repeat cesarean section, amniocentesis
71	96	Carcinoma	–	–	—	—
77	93	Placenta accreta	–	–	—	Chronic hypertension, toxemia with previous pregnancy, repeat cesarean section, amniocentesis
22	85	Permanent sterilization	–	–	—	Repeat cesarean section
83	84	Cervical carcinoma	–	–	Terbutaline, folic acid	Amniocentesis, anemia
Type II (weak reactivity)						
48	73	Repeat cesarean section	900	–	Oxytocin (Pitocin)	Amniocentesis, anemia
64	53	Uterine atony, possible amniotic fluid embolism	10,000	+ (DIC)	Methylergonovine maleate (Methergine), $PGF_{2\alpha}$, blood products, furosemide (Lasix), gentamicin, dopamine, Pitocin	—

All patients were multiparous and had no evidence of hypoxia or sepsis. Coagulopathy was determined by prothrombin time, thromboplastin time, platelet levels, levels of fibrinogen, and fibrin degradation products. Drugs included medications other than those normally used. *MAP*, Lowest mean arterial pressure; *DIC*, disseminated intravascular coagulation.

levels (but not stimulated levels) of cAMP were determined by radioimmunoassay.[10, 11] Stimulated levels of cAMP were not determined because the depessed contractility precluded a correlation between vasorelaxation and stimulated levels of cAMP. Portions of arteries were blotted, weighed, and frozen in liquid nitrogen. Frozen tissue was homogenized in 2 ml of 10% trichloroacetic acid (cold) with a Polytron tissue disruptor at a setting of 6 for 30 seconds. The supernatant was lyophilized and reconstituted in 1 ml of 50 mmol/L sodium acetate, pH 4.75. Aliquots were acetylated and assayed for cAMP by radiommunoassay.

Because endogenous vasodilators and vasoconstrictors may be released from the endothelium, the presence of endothelium was determined by a silver stain technique.[12] Arterial rings proximal and distal to the rings used for the pharmacologic studies were cut open, laid adventitia-side-down, and stained. Other rings were stored in 10% formalin for subsequent paraffin embedding and staining with hematoxylin and eosin.

Norepinephrine-induced constriction was often associated with phasic constrictions (drug-induced oscillatory activity). When norepinephrine-induced oscillatory activity occurred, the lowest tension that developed during the rhythmic activity was taken as the response (i.e., the amplitude of the rhythmic activities was not included in the measurements). Data are presented as mean values ± SE.

All stock solutions and serial dilutions made in Krebs-bicarbonate solution were prepared shortly before the start of each of the experiments. The following drugs were used and were obtained from Sigma Chemical Company, St. Louis: (−)-arterenol bitartrate, indomethacin, and methylene blue, $PGF_{2\alpha}$, [Arg^8]-vasopressin acetate, DL-propranolol hydrochloride, histamine diphosphate, and 5-hydroxytryptamine creatinine sulfate.

Results

The patients were divided into three categories. The control patients were considered type I. The hemorrhaging patients were divided into types II and III on

Table I—Cont'd

06	57	Retained products of conception	4000	Thrombocytopenia	$PGF_{2\alpha}$, blood products, ampicillin, gentamicin	History of intravenous drug abuse and hepatitis B, chronic inflammation of endometrium and myometrium, lymphocyte infiltration of myometrium
75	66	Placenta accreta, secondary vaginal and uterine laceration	5000	+ (DIC)	Methergine, $PGF_{2\alpha}$, blood products, gentamicin, (Cleocin), magnesium sulfate	Delivery at home, breech birth
82	77	Uterine atony	3200	+ (DIC)	Methergine, $PGE_{2\alpha}$, ephedrine, Pitressin, blood products, albumin, magnesium sulfate, hydralazine	Repeat cesarean section, chronic anemia, chronic cervicitis
Type III (no reactivity)						
01	88	Abnormal placental implantation	2000	–	Pitocin, $PGF_{2\alpha}$, prostaglandin E_2	—
26	76	Uterine atony	1500	–	Methergine, $PGF_{2\alpha}$, prostaglandin E_2, Pitocin	Amniocentesis, repeat cesarean section, anemia

the basis of reactivity of the isolated uterine artery. Types II and III were not associated with any particular diagnosis, parity, presence of coagulopathies, or depressed mean arterial blood pressure (Table I).

The uterine arteries from the control patients (type I, $n = 9$) responded with a maximum or near-maximum constriction to norepinephrine (30 μmol/L, 3.6 ± 1 gm), potassium chloride (75 mmol/L, 10.2 ± 3 gm), and arginine vasopressin (1 μmol/L, 18.8 ± 2.6 gm). In uterine arteries from five patients with uncontrollable bleeding (type II), the constrictor responses to the same drugs were markedly depressed: norepinephrine (30 μmol/L, 0.5 ± 0.2 gm), potassium chloride (75 mmol/L, 1.9 ± 0.8 gm), $PGF_{2\alpha}$ (30 μmol/L, 0 gm) and arginine vasopressin (1 μmol/L, 0.2 ± 0.05 gm). Uterine arteries from two patients (type III) exhibited no constrictor responses to norepinephrine (30 μmol/L), potassium chloride (75 mmol/L), $PGF_{2\alpha}$ (30 μmol/L), or arginine vasopressin (1 μmol/L). Records of experiments that used uterine arteries from the three categories of patients are shown in Fig. 1. The results from the experiments are summarized in Fig. 2. When the concentrations of the constrictor drugs were increased, little or no further increases in constriction were observed. In preliminary studies that used uterine arteries from patients with uncontrollable uterine bleeding various concentrations of the drugs were used but no responses were elicited except at higher concentrations. The depressed responses to the various vasoconstrictors persisted, in spite of continual suffusion and repeated administration of the drugs for 8 to 12 hours.

Other constrictor agents (serotonin, 30 μmol/L; calcium chloride, 4 mmol/L; histamine, 30 μmol/L) were used in a few of the uterine arteries from patients with obstetric hemorrhage (types II and III). None of these agents induced constriction. The impaired response to norepinephrine was not reversed by indomethacin (1 μmol/L), which is an inhibitor of prostaglandin synthetase; by methylene blue (10 μmol/L), which is a blocker of endothelium-derived relaxing factor activation of guanylate cyclase; or by propranolol (1 μmol/L), an antagonist of β-adrenergic receptors (Fig. 3).

The basal concentrations of cAMP were 152.7 ± 1.4 pmol/gm wet weight in uterine arteries ($n = 3$) from patients with obstetric hemorrhage and 170.3 ± 4.5 pmol/gm wet weight in uterine arteries ($n = 3$) from control patients.

The intimal surface of the arterial rings was examined microscopically *en face* after application of a silver stain to ascertain the presence of endothelial cells. Almost all the intimal surface of the rings was covered by endothelial cells as demonstrated by "black" cell borders. In the tissues that were embedded, stained, and examined at a magnification of ×40, there did not

appear to be any differences in the endothelial and smooth muscle layers of the arteries from type I (control) patients ($n = 3$) or type II ($n = 1$) or III (hemorrhaging) patients ($n = 2$).

Comment

During obstetric hemorrhage the patient is often given drugs to increase uterine tone. These drugs, including oxytocin, ergot alkaloids, vasopressin (Pitressin), and $PGF_{2\alpha}$, have vasoconstrictor action. The patients may also receive vasopressors such as ephedrine and phenylephrine. In this study isolated uterine arteries from patients experiencing obstetric hemorrhage demonstrated depressed or lack of reactivity to some of the same vasoconstrictor drugs used in the patient. To our knowledge this is the first report of such an altered reactivity in the isolated uterine vasculature of patients with obstetric hemorrhage compared with pregnant patients who undergo cesarean hysterectomy for other medical reasons.

This study involved only uterine arteries from pregnant patients, which eliminates the variability in results that may occur when pregnant and nonpregnant conditions are compared. We have previously shown that the norepinephrine or potassium chloride concentration that produced 50% of the maximal contraction and the maximal contractile response to norepinephrine or potassium chloride are similar in uterine arteries from pregnant and nonpregnant patients.[2, 3] However, other studies comparing pregnant and nonpregnant condi-

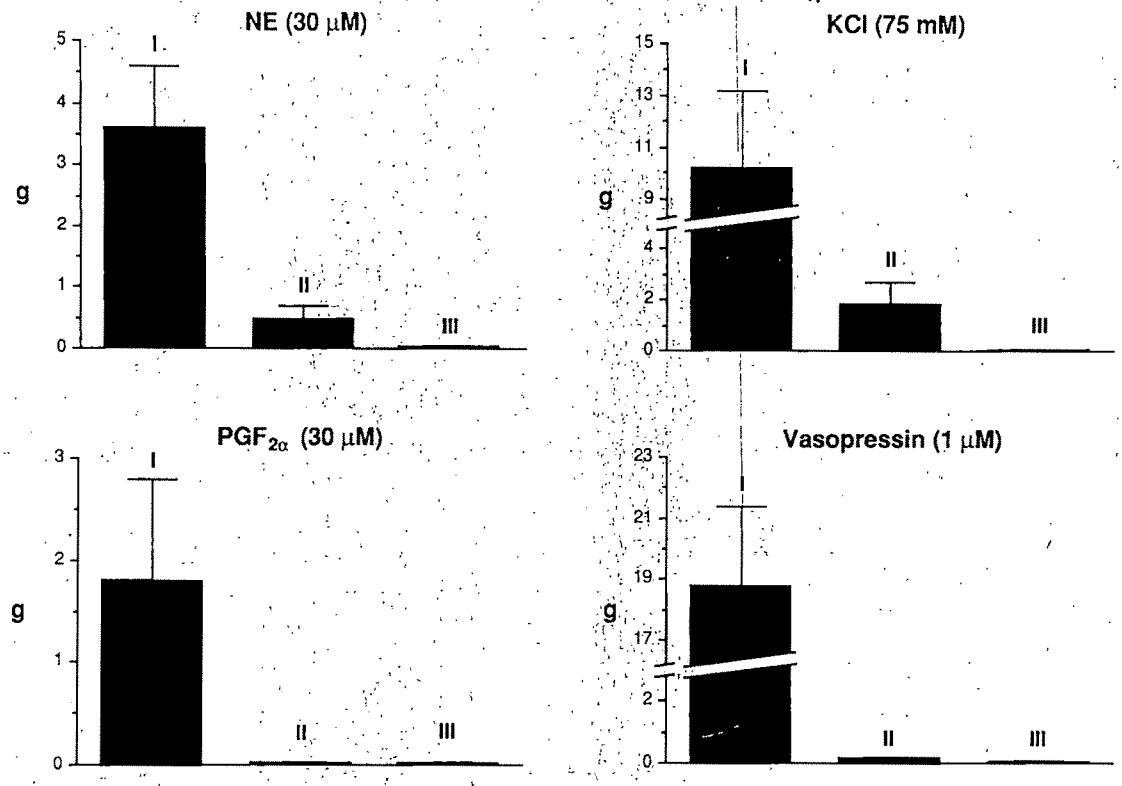

Fig. 2. Summary of results showing depressed constrictions induced by vasoconstrictors that act through various mechanisms in uterine arteries from patients with obstetric hemorrhage. Data were obtained from experiments similar to those shown in Fig. 1. Each *bar* represents constrictor response in grams (*g*) produced by vasoconstrictor and is mean ± SE of data from various patient types (*I*, $n = 9$; *II*, $n = 5$; *III*, $n = 2$).

tions show a variability in the constrictor responses to drugs such as norepinephrine, phenylephrine, or $PGF_{2\alpha}$ in uterine arteries from pregnant sheep,[13-17] rabbits,[18] and guinea pigs.[19]

An effort was made to determine the mechanism for the depressed reactivity in the uterine arteries from the patients experiencing hemorrhage. Agents were used that have been shown to produce vasoconstriction by different mechanisms such as activation of receptor-operated and/or voltage-dependent calcium channels as well as the release of calcium from intracellular storage sites. These various compounds produced no or only low constrictions. The results suggest that the depressed mechanism is common to all of the constrictors. Thus perhaps the contractile machinery itself is impaired.

It is possible that these uterine arteries from patients experiencing obstetric hemorrhage may have elevated levels of an endogenous vasodilator that is continuously released. We have previously reported that endothelium-derived relaxing factor production or release is increased in uterine arteries from normal pregnant patients when compared with that of nonpregnant patients.[4] However, in the uterine arteries from patients with hemorrhage, methylene blue (an inhibitor of the action of endothelium-derived relaxing factor or nitric oxide on soluble guanylate cyclase)[20] did not increase the baseline or enhance the subsequent response to norepinephrine to any greater extent than it did in normal pregnant uterine arteries. Furthermore, indomethacin, a cyclooxygenase inhibitor, did not increase the baseline or increase the constrictor response to norepinephrine, which indicates that an endogenous vasodilator prostaglandin was not continuously released or released with exposure to norepinephrine.

In other blood vessels the β_2-adrenergic receptor has been shown to mediate vasodilatation. Norepinephrine has a low affinity for the vasodilatory β_2-adrenergic receptor but a high affinity for the β_1-adrenergic receptor. Propranolol, a nonselective β-adrenergic receptor antagonist, was used to determine whether there was an increased affinity of the β_2-adrenergic receptor for norepinephrine or a change in the subtype from β_2 to β_1 in the uterine arteries that showed depressed norepinephrine-induced constrictions. Such changes would be reflected in a depressed norepinephrine-induced constriction. However, the response to norepinephrine was unaffected by the presence of propran-

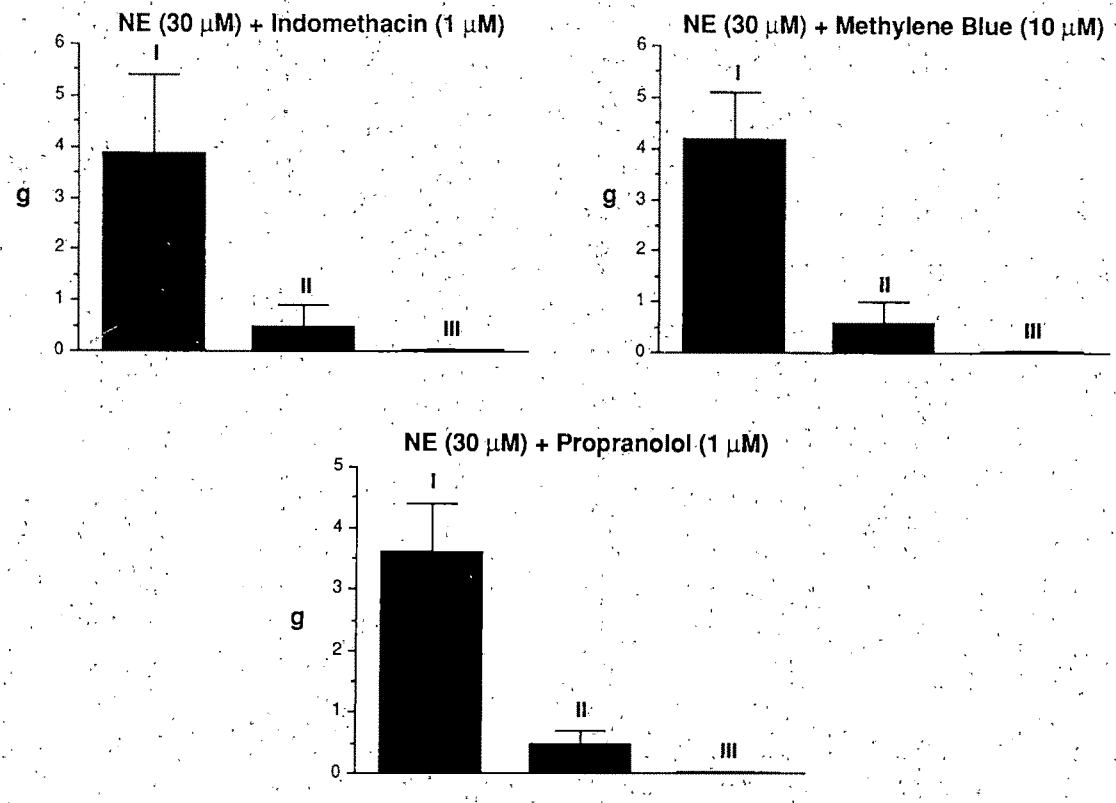

Fig. 3. Lack of effect of inhibitors of various vasodilator mechanisms. Norepinephrine (30 μmol/L) was administered for 15 minutes in absence and presence of inhibitor. Inhibitor was present for 30 minutes before norepinephrine was readministered. Each *bar* represents constrictor response to norepinephrine in grams *(g)* in presence of inhibitor (*I*, $n = 9$; *II*, $n = 5$; *III*, $n = 2$).

olol. Thus it appears that in the uterine arteries, as well as in other blood vessels, norepinephrine is selective for the β_1-adrenergic receptor and that there is no change in the β-adrenergic receptor subtype in the uterine arteries from patients with obstetric hemorrhage.

Numerous studies have shown a good correlation between cAMP concentrations in blood vessels and the degree of relaxation produced by stimulators of adenylate cyclase (e.g., isoproterenol). The basal levels of cAMP were not elevated in the uterine arteries from the patients with hemorrhage compared with those of uterine arteries from control pregnant patients. Hence our results exclude the possibilities that overstimulation of adenylate cyclase or dysfunctional adenylate cyclase or its regulatory G proteins (Gi or Gs) may be involved in the depression of contractility in the uterine arteries.

The mechanism for the depressed or lack of reactivity of the uterine arteries from hemorrhaging patients remains unclear. In a review of the charts of the patients, no risk factors could be found that were common to all of the hemorrhaging (types II and III) patients. Risk factors included causes of obstetric hemorrhage, presence of infection, development of hemorrhagic shock (volume of blood loss and fall in mean arterial pressure), parity, drugs, and associated clinical phenomena. Histologically, there did not appear to be any differences in the intimal or medial layers in the uterine arteries. Furthermore, the depressed or lack of reactivity could not be washed out from the isolated uterine vessels with time.

It is generally thought that obstetric hemorrhage is associated with a number of causes such as uterine atony, abnormal placentation, trauma during labor and delivery, and coagulation defects.[1] The results of this study, which used isolated uterine arteries from patients experiencing obstetric hemorrhage, suggest that these uterine arteries have lost their ability to constrict as a result of an unidentified mechanism. Failure of uterine artery constriction may contribute to uncontrollable obstetric hemorrhage.

A reevaluation of estrogen status in postmenopausal women who smoke

Denise Lee Cassidenti, MD, Malcolm C. Pike, PhD, Ariel G. Vijod, MS, Frank Z. Stanczyk, PhD, and Rogerio A. Lobo, MD

Los Angeles, California

Hypoestrogenism in postmenopausal smokers has been suggested as the mechanism for the observed decreased risk of endometrial cancer and increased risk of osteoporosis. We have prospectively studied a well-matched group of smokers and nonsmokers and have evaluated their estrogen levels and compared them with existing data from the literature. We conclude that increased adrenal activity resulting in increased androgens, mainly androstenedione, is seen in postmenopausal smokers but that estrogen levels are not decreased. We hypothesize that in nonusers, unlike in users of estrogen, smoking is not associated with changes in estrogen levels and that other mechanisms must be responsible for the epidemiologic observations seen. (AM J OBSTET GYNECOL 1992;166:1444-8.)

Key words: Smoking, postmenopausal women, hormonal status

Recent studies have shown that postmenopausal women who smoke have a decreased risk of endometrial cancer and an increased risk of osteoporosis.[1,2] It has been assumed that the mechanism for these observations is profound hypoestrogenism, with levels of estrogen being lower in postmenopausal women who smoke. Our recent study[3] and data from others[4-8] suggest that among users of oral estrogen hepatic metabolism of estrogen is increased with smoking, which results in lower estrogen levels.[3-8] However, we hypothesize here that smoking in nonusers of estrogen does not result in lower estrogen levels, and therefore other mechanisms for the epidemiologic findings need to be entertained. To this end, we have prospectively studied a well-matched population of postmenopausal women not taking estrogen who were either smokers or nonsmokers and have evaluated their hormonal status. We have also compared and combined our data with the findings of other investigators in the literature.

Material and methods

Subjects. Thirty-eight postmenopausal women agreed to participate in this study in response to individual letters sent to members of a retirement community in the Los Angeles area. All women had been postmenopausal for ≥5 years. None had received hormonal replacement therapy, prednisone, cortisone, or anticoagulants for 6 months before the study. All patients were healthy and had no prior history of cancer or chronic illness. Seventeen women were nonsmokers, and 21 were chronic smokers who reported smoking an average of 19.9 cigarettes per day (Table I).

Protocol. Volunteers were studied in the morning after they had eaten their usual breakfast. Smokers did not smoke on the morning of the study before baseline testing (approximately 8 AM). Blood samples were drawn at baseline and 3 hours later. During these 3 hours smokers were instructed to smoke five of their usual brand of cigarettes. Sera obtained were separated and stored at −20° until assayed. Values for tar and nicotine content on brands of cigarettes were obtained from the United States Federal Trade Commission Report.[9]

Assays. All samples were assayed for estrone, estradiol, the estrogen conjugate estrone glucuronide, androstenedione, dehydroepiandrosterone sulfate (DHEAS), cortisol, sex hormone–binding globulin (SHBG), and non-SHBG-bound estradiol.

Estrone, estradiol, androstenedione, non-SHBG-bound estradiol, and SHBG levels were measured in serum by previously validated assays.[10-15] Estrone and androstenedione were measured by radioimmunoassay (RIA) after diethyl ether extraction and Celite chromatography. Estradiol was measured by RIA after extraction with ethyl acetate/hexane (4:6, vol/vol), by means of an iodinated estrone kit from Pantex (Santa Monica, Calif.). Tritiated estradiol was added to the aliquot of serum in which non-SHBG-bound estradiol was measured. All labeled and unlabeled estradiol bound to SHBG was precipitated. The remaining labeled unbound and non-SHBG-bound estradiol in the supernatant was counted and expressed as a percent of the total tritiated estradiol added. The resulting per-

centage was multiplied by the serum estradiol to determine non-SGHB-bound estradiol in picograms/milliliter. SHBG was quantitated by determining its binding affinity to dihydrotestosterone in 0.1 ml of serum with the charcoal technique, which uses the temperature-dependent properties of proteins. The interassay coefficient of variation determined in pooled serum was 13% for estrone, 13% for estradiol, 12% for androstenedione, 10% for non-SHBG-bound estradiol, and 13% for SHBG.

Estrone glucuronide was measured in an aliquot of 0.6 ml of serum combined with an internal standard of approximately 1000 disintegrations/min tritiated estradiol glucuronide (Amersham Laboratories, Buckinghamshire, England; specific activity 12.6 Ci/mmol) and dissolved in 0.1 ml of 0.2 mol/L sodium phosphate buffer, pH 6.8, to monitor procedural losses, then incubated at 37° C for 30 minutes. Two milliliters phosphate buffer is added to the aqueous layer after extraction to remove unconjugated steroids. To each sample 500 U of β-glucuronidase (type VII-A from *Escherichia coli*, Sigma Chemical Company, St. Louis) in 0.1 ml of phosphate buffer was added and incubated 16 to 18 hours at 37° C. The hydrolyzed estrogens were extracted twice with 5 ml ethyl acetate/hexane (4:6, vol/vol). After the organic solvents were evaporated, the extract was reconstituted and the estrone was measured as previously described. All values are corrected for molecular weight. The sensitivity of the assay, defined as the smallest amount of estrone glucuronide per RIA tube that reduces the number of counts per minute of tritiated estrone glucuronide bound at zero mass by 2 SD, was 3.9 pg per tube or 45 pg/ml. Accuracy of the RIA was established as follows. Known quantities of authentic estrone glucuronide was added to aliquots of pooled serum. Linear regression analysis of the estrone glucuronide measured in pooled serum versus the amount of conjugated steroid added was done. A correlation coefficient of 0.99 was obtained. The specificity of the enzyme was 0.27% for conjugated sulfates. The interassay coefficient of variation for estrone glucuronide was 10%.

Serum DHEAS was determined by RIA as previously described.[16, 17] Cortisol was measured by RIA after its extraction from serum (0.01 ml) with ethyl acetate/hexane (1:1, vol/vol). The antiserum was raised against cortisol-3-(*O*-carboxymethyl)oxime-bovine serum albumin (ICN/RSL, Irvine, Calif.) and was used in conjunction with tritiated cortisol (DuPont NEN Research Products, Boston; specific activity 45 Ci/mmol). The antibody-bound cortisol was separated from the unbound with dextran-coated charcoal. The interassay coefficient of variation for DHEAS and cortisol were 16.4% and 12.1%, respectively.

The ratio, androstenedione/estrone, was calculated as a measure of aromatase activity.

Table I. Characteristics of volunteers population

	Nonsmokers	*Smokers*
No.	17	21
Age (yr)	72.3 ± 2.3	68.8 ± 3.9
Weight (kg)	62.9 ± 9.3	64.1 ± 7.1
Height (m)	1.59 ± 0.04	1.60 ± 0.07
Cigarettes (No./day)	0	19.9 ± 8.3
Tar (mg/day)	0	204 ± 155
Nicotine (mg/day)	0	14.9 ± 11.1

*Values are mean ± SD.

Statistical analyses. All hormonal measurements were transformed to logarithmic values to approximate normal distributions for statistical analysis. Group values are reported as geometric mean concentrations. Standard statistical methods of analysis of variance (and covariance) were used in the analysis of the results. All p values quoted are two-sided.

Results

The characteristics of the postmenopausal women sampled are shown in Table I. The mean age was 72.3 years for the nonsmokers and 68.8 years among smokers; this was not statistically significant. The groups were well matched for height and weight. Smokers averaged 19.9 cigarettes per day with an average tar of 204 mg per day and an average nicotine of 14.9 mg per day.

The geometric mean hormone levels of the nonsmokers and smokers are given in Table II. When smokers are compared with nonsmokers, estrone was 13% lower at baseline and 6% lower after smoking. These changes, however, were not statistically significant. Estrone glucuronide values were similar in smokers and nonsmokers, being only 5% and 4% greater before and after smoking. Estradiol changes were also not significant. They were 5% greater and 1% less before and after smoking. SHBG was 22% lower at 8 AM and 11% lower at 11 AM in smokers, but this also was not statistically significant. Bioavailable non-SHBG-bound estradiol was not significantly different in smokers and nonsmokers.

Androstenedione was 28% higher at 8 AM in smokers ($p = 0.13$) and 52% higher at 11 AM (after the smokers had smoked five cigarettes over a 3-hour period, $p = 0.011$). Nonsmokers showed a decrease in androstenedione over time (492 pg/ml at 8 AM vs 404 pg/ml at 11 AM, $p = 0.13$); the decline was much less in smokers (628 vs 614 pg/ml).

DHEAS was 42% higher at 8 AM and 62% higher at 11 AM in smokers than in nonsmokers, but these results did not achieve statistical significance. Cortisol was 3% lower at 8 AM in smokers than in nonsmokers but 19% higher at 11 AM (after smoking). This also was not statistically significant. As expected, cortisol showed a

marked decrease over a 3-hour period in nonsmokers (16.1 vs 11.7 μg/dl, $p = 0.017$); the decline was much less in smokers (15.7 vs 13.9 μg/dl). Smokers showed a 47% higher androstenedione/estrone ratio at baseline ($p = 0.026$) and a 61% higher ratio after smoking ($p = 0.009$).

The results shown in Table II remained essentially unchanged after adjustment for age, age at menopause, weight, height, and alcohol consumption.

Comment

The data presented here suggest that in postmenopausal women who smoke there is no alteration in serum estrogen levels if they are not receiving hormonal replacement. Our data suggest that the effect of smoking on serum hormone levels in healthy postmenopausal women is an increase in adrenal androgens (androstenedione, DHEAS). This is evident at baseline (androstenedione, 28% increase; DHEAS, 42% increase) and to a greater extent later in the morning after smoking (androstenedione, 52% increase; DHEAS, 62% increase). There is evidence for an increased level of cortisol in smokers compared with nonsmokers. The normal diurnal decline of cortisol is blunted in the smoking group.

There have been at least four other comparative studies of serum hormone levels in postmenopausal smokers and nonsmokers.[6-8, 18] Some details and results of these studies together with our results are given in Table III.

All studies that have looked at serum androstenedione have found elevated levels in smokers (mean increase at 20 cigarettes per day of 41%, $p < 0.0001$, Table III). This 41% mean value may be too high, because the biggest effect was seen in the study of Friedman et al.[7] and their smoking study subjects were close to menopause and 5 years younger than their nonsmoking subjects. This discrepancy will tend to exaggerate any difference between smokers and nonsmokers as androstenedione declines at menopause and with increasing age. When the results of Friedman et al.[7] are excluded, the mean increase in androstenedione in smokers is 37% ($p = 0.0002$).

Friedman et al.[7] and Khaw et al.[6] also found, as we did, that DHEAS levels are elevated in smokers; however, Key et al.[18] did not. There is no obvious reason for the discrepancy between these studies. The subjects described by Key et al.[18] tended to be samples later in the day than the subjects in the other studies, but we know of no reason why this should be of any importance. Key et al.[18] did provide some evidence for adrenal activation in smokers; however, urinary 11-hydroxyketosteroids were increased. When the combined data are considered, the mean increase in DHEAS at 20 cigarettes per day is 18% ($p = 0.059$, Table III). The results of Friedman et al.[7] may again be considered suspect for the reasons given above, and when their results are excluded, the mean increase in DHEAS in smokers is 14% ($p = 0.15$).

Cortisol was elevated in our smokers but only at 11 AM after smoking. The smokers reported by Friedman et al.[7] had elevated baseline levels. We have no explanation for this discrepancy. When all the available data are examined, changes in androstenedione, DHEAS, and cortisol all appear to be higher in smokers.

When the results are taken together, there does not

§Kilograms per square meter.

appear to be any effect of smoking on estrone and estradiol in postmenopausal women who are not receiving oral estrogen. It has been suggested that catechol estrogen metabolism is enhanced in smokers[19]; however, if this was a significant finding, we would expect that it would have resulted in a difference in estrogen levels, an effect that has not been observed. That serum estrone glucuronide and SHBG levels were also not increased in smoking women suggests that the enhancement in hepatic activity, which occurs with smoking, occurs only in oral estrogen users.

Our results, however, show that the androstenedione/estrone ratio distinguishes smokers from nonsmokers more effectively than androstenedione alone. This is consistent with experimental data of nicotine-inhibiting aromatase activity.[20,21] Because aromatase activity is decreased by smoking, we would expect the estrogen status of smokers to be decreased. However, because adrenal activity is enhanced, particularly androstenedione, estrogen levels are similar in smokers and nonsmokers.

Therefore current results suggest that smoking increases adrenal androgen levels (androstenedione, DHEAS) and, at least transiently, cortisol increases as well. How do these results explain the epidemiologic observations of the markedly reduced risk of endometrial cancer[1] and the markedly increased risk of osteoporosis[2] in smokers? We hypothesize here that these observations are not based on changes in estrogen status but rather on alterations in other systems.

There is no evidence that cortisol has an influence on endometrial tissue, but there is some evidence that androgens can inhibit estrogen-mediated effects in the rat uterus.[22] In one study[22] it was shown that dihydrotestosterone inhibited estrogen-mediated rat uterine growth, and this effect appeared to be due to a dihydrotestosterone-induced reduction in estrogen-induced ribonucleic acid transcription rather than to any inhibition of estrogen receptor synthesis (as is true of progesterone). The only relevant epidemiologic data of androgen levels in endometrial cancer have been reported by Judd et al.[23] They found no reduction in androstenedione in endometrial cancer cases as would be expected if androstenedione antagonized the effect of estrone in endometrial tissue. Indeed, there is evidence that some patients with endometrial cancer have increased androgen levels, which may be related to hyperinsulinemia.[24] The obese insulin-resistant patient may in fact have an additional risk factor because insulin may stimulate endometrial aromatase activity.[25] Although androgens may still be inhibitory to estrogen action in the endometrium of normal-weight women who smoke, there are probably other mechanisms to explain the epidemiologic observations.

Reasons that smokers are at greater risk of osteoporosis may be due to the relative cortisol excess in smokers. Smoking itself may also have direct toxic (carbon monoxide, nicotine) effects on bone cells, thereby leading directly to osteoporosis. It is well known that smoking is toxic to other tissues; e.g., smoking influ-

ences oocyte atresia[26] and may impair sperm density, motility, and morphologic features.[27] However, increased androstenedione levels would tend to be beneficial to bone.

In conclusion, we suggest that estrogen levels are not decreased in nonusers of oral estrogen and therefore may not be implicated in the associated epidemiologic findings of a decrease in endometrial cancer and an increase in osteoporosis. Our findings and those of others reviewed here strongly suggest that there is increased adrenal activity in smoking women. This, as well as direct toxic effects of smoking, may be associated with the epidemiologic observations. More studies should be directed at these other mechanisms rather than at alterations in estrogen metabolism.

Addendum

In our patients we more recently measured 24-hour urinary estriol and estrone to assess whether estrogen metabolism may be altered (lowered 16-hydroxylase activity, thus favoring 2-hydroxylase), as suggested previously.[19] The 42% decrease in the estriol/estrone ratio described[19] suggested enhancement of the conversion to catechol estrogens; however, we found only a 6% decrease. The ratio was 1.028 in nonsmokers and 0.963 in smokers ($\dot{p} = 0.37$).

Human fetal bilirubin levels and fetal hemolytic disease

Carl P. Weiner, MD
Iowa City, Iowa

The development of secondary fetal anemia in association with maternal red blood cell alloimmunization requires hemolysis. In specimens obtained at the time of a clinically indicated cordocentesis, total and direct umbilical venous bilirubin was measured and the indirect umbilical venous bilirubin calculated in 43 antigen-positive and 30 control fetuses. Twenty-two (51%) of the antigen-positive fetuses had or subsequently developed severe anemia (hematocrit <30%). Umbilical venous total bilirubin ($r = 0.47$, $p = 0.0008$) and direct bilirubin ($r = 0.520$, $p = 0.04$) levels each rose with gestation. Indirect bilirubin did not vary significantly with gestation. Bilirubin was unrelated to hemoglobin. In contrast to the control fetuses, umbilical venous total bilirubin for antigen-positive fetuses was inversely related to hemoglobin ($r = -0.57$, $p < 0.0001$) independent of gestational age ($r = 0.53$, $p < 0.0001$) (multiple R of hemoglobin and gestational age for umbilical venous total bilirubin = 0.76, $p < 0.0001$). Eighteen of 22 (82%) fetuses in whom anemia developed had an umbilical venous total bilirubin ≥97.5 percentile compared with only eight of 21 (38%) fetuses in whom anemia did not develop ($p = 0.009$). In longitudinal study the umbilical venous total bilirubin frequently rose above normal weeks before the development of anemia. An umbilical venous total bilirubin >3 mg/dl represented the warning line. Fifteen of 16 (94%) fetuses in whom either severe antenatal anemia or significant postnatal hyperbilirubinemia developed had an umbilical venous total bilirubin >3 mg/dl. We conclude that the normal placental capacity for the transport of fetal bilirubin is exceeded in the face of enhanced fetal hemolysis. An elevated fetal bilirubin often precedes the development of antenatal anemia. The antigen-positive fetus with an elevated bilirubin is at high risk to develop anemia antenatally. (Am J Obstet Gynecol 1992;166:1449-54.)

Key words: Fetus, bilirubin, hemolytic anemia, alloimmunization, cordocentesis

Although the fetal response to maternal red blood cell alloimmunization depends on several factors, including the quantity of antibody bound to the fetal red blood cell and the rate of red blood cell production,[1] the development of fetal anemia ultimately requires hemolysis. In a preliminary study our unit observed that the normal fetal concentration of bilirubin exceeded that of the neonate.[2] This suggested that the placental capacity for fetal bilirubin clearance was limited. The purposes of this investigation were to determine (1) the concentration of fetal bilirubin across gestation, (2) whether antigen-positive fetuses of alloimmunized women have higher bilirubin concentrations than control fetuses, and (3) whether a high bilirubin concentration preceded the development of fetal anemia.

Material and methods

Cordocentesis was performed in 73 pregnancies with referral to the University of Iowa Fetal Diagnosis and Treatment Unit. Forty-three antigen-positive fetuses at risk for hemolytic anemia were sampled (95 specimens) to determine the severity of their disease as described previously.[1] The remaining 30 fetuses were sampled once for a variety of indications (most commonly maternal red cell or platelet alloimmunization) and shown to be free of disease.

Laboratory measurements performed in the central hospital laboratory included total bilirubin, direct bilirubin, and a complete blood cell count. The indirect bilirubin was calculated. Total and direct bilirubin (mg/dl) were measured in serum by a commercially available colorimetric assay (Boehringer-Mannheim) on an autoanalyzer (Hitachi 737). Hemolyzed samples were excluded. The complete blood cell count was performed with an autoanalyzer (Technicon H-1) on blood anticoagulated with ethylenediaminetetraacetic acid. Because of the limited sample volume, not all tests could be performed on each occasion.

The technique for cordocentesis has previously been detailed.[3] Briefly, a 22-gauge spinal needle was held in the ultrasonographic plane of a 5 MHz sector transducer with a fixed-needle guide (CIVCO, Kalona, Ia.).

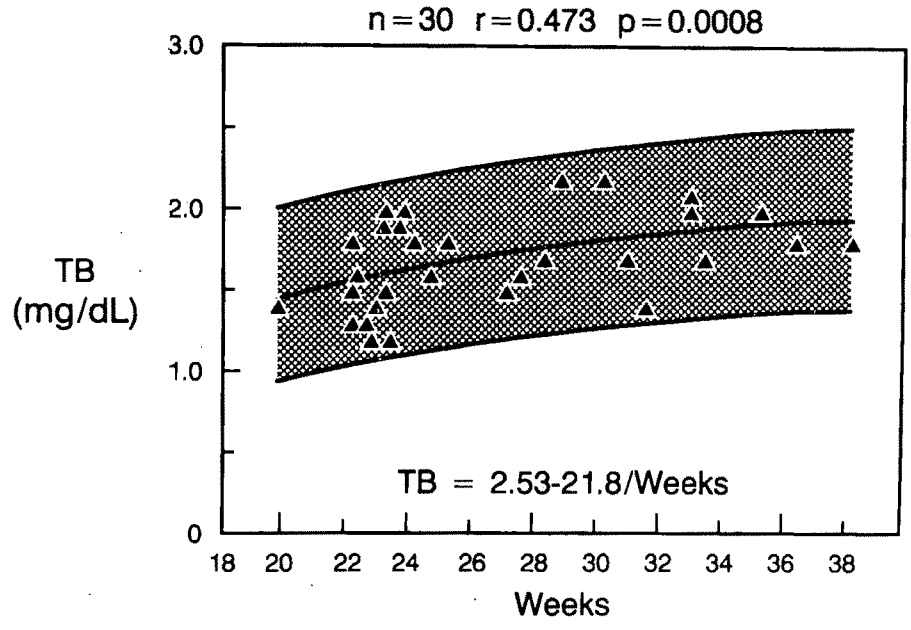

Fig. 1. Prediction interval (95%) for umbilical venous serum total bilirubin *(TB)* in healthy, antigen-negative fetuses ($n = 30$). There was no relationship between bilirubin and hemoglobin in this group.

The umbilical vein was preferred over the umbilical artery to minimize the risk of a procedure-related bradycardia.[3] Pancuronium (0.3 mg/kg estimated fetal weight) was administered intravenously whenever fetal movement was felt to pose a risk.

All records were maintained prospectively in a computerized data base whose veracity was confirmed on a regular basis. The results are presented as the mean ± SD unless otherwise stated. One hundred eleven of 125 (90.2%) specimens were from the umbilical vein. Only the first measurement from each antigen-positive fetus was included in the search for a relationship between bilirubin and both hemoglobin and gestational age. Because the small number of arterial specimens precluded an accurate comparison of arterial and venous samples controlling for gestational age, the statistical analyses presented here were limited to specimens from the umbilical vein. The 95% prediction interval of bilirubin for control fetuses was based on the regression obtained using bilirubin as the dependent variable and gestational age as the independent variable. Subsequent bilirubin measurements from antigen-positive, not transfused, fetuses were graphed to reveal the natural history. An analysis of covariance was used to compare the bilirubin slopes of antigen-positive and control fetuses. Receptor-operated curves were applied to determine the umbilical venous total bilirubin concentration most predictive of a fetal or neonatal hemolytic complication. Other analyses included independent t test, stepwise multiple regression, and cross tabulation. A p value ≤ 0.05 was considered to indicate a significant difference.

Results

The mean gestational age of fetuses at risk for hemolytic anemia was 24.9 ± 3 weeks and ranged from 20 to 36 weeks. Twenty-two (51%) developed a hematocrit <30% and were considered candidates for transfusion therapy.[4] The mean gestational age of the control group was 27 ± 5 weeks and ranged from 20 to 38 weeks.

Umbilical venous total bilirubin ($r = 0.47$, $p < 0.0008$, $n = 30$) (Fig. 1) and direct bilirubin ($r = 0.52$, $p = 0.04$, $n = 15$) for the control group rose progressively with advancing gestation and were unrelated to the fetal hemoglobin. Indirect bilirubin did not change significantly with gestation (mean 1.4 ± 0.3 mg/dl, $n = 15$).

In contrast to the control fetuses, umbilical venous total bilirubin from antigen-positive fetuses was inversely related to hemoglobin ($r = -0.57$, $p < 0.0001$) (Fig. 2) independent of gestational age ($r = 0.53$, $p < 0.0001$) (multiple R of hemoglobin and gestational age for umbilical venous total bilirubin = 0.76, $p < 0.0001$). There was no relationship between hemoglobin and gestational age in the antigen-positive fetuses ($r = 0.05$, $p = 0.75$). Although there was a significant relationship between umbilical venous total bilirubin and gestational age in both groups, they were different (Fig. 3). Umbilical venous total bilirubin in antigen-positive fetuses rose at a rate significantly greater ($p < 0.01$) than that expected for the normal gestational increment. A similar association was also observed for both the direct and indirect bilirubin concentrations and hemoglobin and gestational age (Table

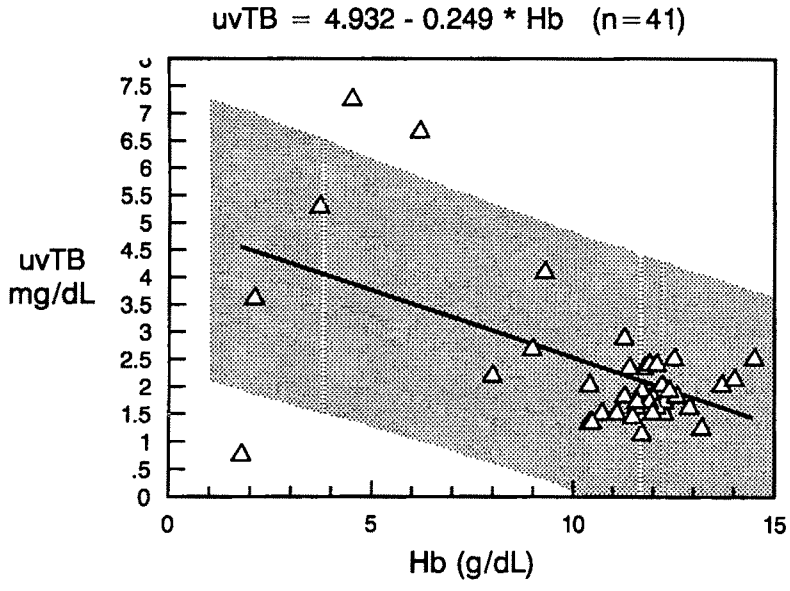

Fig. 2. Relationship between total umbilical venous bilirubin *(uvTB)* and hemoglobin *(Hb)* in antigen-positive fetuses. The higher the bilirubin concentration, the lower the fetal hemoglobin. Note that total bilirubin of 3 mg/dl approximates hemoglobin of 8 gm/dl (two missing values).

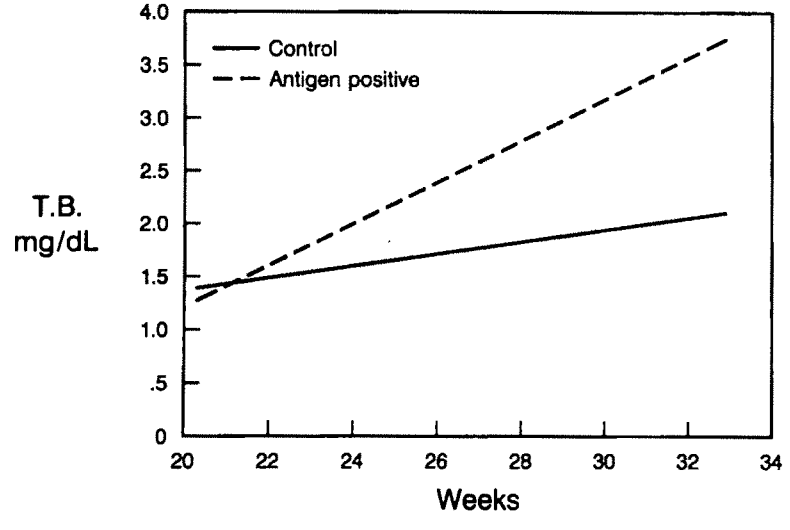

Fig. 3. Regression lines for umbilical venous total bilirubin *(T.B.)* and gestational age in control and antigen-positive groups. Antigen-positive fetuses have steeper slope. This demonstrates that severity of fetal hemolytic disease was progressive.

I). Because the relationships between indirect and direct bilirubin for hemoglobin in antigen-positive fetuses were similar to that for umbilical venous total bilirubin, we have focused on the latter because of the larger sample size.

The umbilical venous total bilirubin exceeded the 97.5 percentile in 18 of 22 (82%) of antigen-positive fetuses who developed a hematocrit <30%. In eight of 10 fetuses with two or more samples, the elevation preceded the development of anemia by several weeks (Fig. 4). In contrast, only eight of 21 (38%) of fetuses who did not develop severe anemia had an umbilical venous total bilirubin above the 97.5 percentile at any time before delivery ($p = 0.009$ from fetuses who required transfusion) (Fig. 5). Overall, the positive predictive value of a high umbilical venous total bilirubin for the development of severe fetal hemolytic anemia was 69% (18 of 26), and the negative predictive value of a low umbilical venous total bilirubin for the development of severe anemia was 76% (13 of 17).

We sought to determine whether the clinical application of the umbilical venous total bilirubin measurement could be further simplified by the identification of a warning line. An umbilical venous total bilirubin

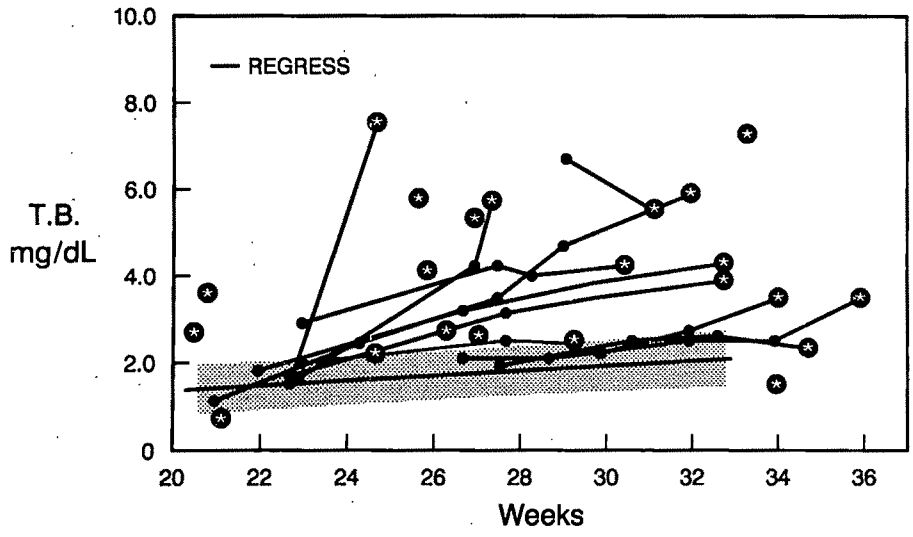

Fig. 4. Serial umbilical venous total bilirubin *(T.B.)* concentrations in fetuses who developed severe hemolytic anemia. Last sample *(asterisk)* indicates that hematocrit had declined below 30%. Single samples indicate that initial hematocrit was <30% first time bilirubin was measured. *Shaded area* reflects 95% prediction interval for normal range. Note that elevated umbilical venous total bilirubin often preceded development of anemia severe enough to require transfusion.

Table I. Relationship between bilirubin, hemoglobin, and gestation in first sample from antigen-positive fetuses

Bilirubin group	*No.*	*R*	*p*	*r*	*p*
Total	43	0.76	<0.0001		
Hemoglobin				−0.57	<0.0001
Weeks' gestation				0.53	<0.0001
Direct	39	0.68	<0.0001		
Hemoglobin				−0.53	0.0001
Weeks' gestation				0.46	0.0007
Indirect	39	0.74	<0.0001		
Hemoglobin				−0.56	<0.0001
Weeks' gestation				0.52	<0.0001

>3 mg/dl exceeded the 97.5 percentile for all gestational ages. Six fetuses already had severe anemia when first sampled: five of the six (83%) had an umbilical venous total bilirubin ≥3 mg/dl. The umbilical venous total bilirubin ultimately rose above 3 mg/dl in another nine fetuses whose initial hematocrit was >30% and whose initial umbilical venous total bilirubin <3 mg/dl. Seven of these nine (78%) developed severe hemolytic anemia antenatally. The two fetuses who did not develop anemia antenatally experienced severe hyperbilirubinemia postnatally (one required two double-volume exchange transfusions and the other required 10 days of phototherapy). Fetuses whose umbilical venous total bilirubin before transfusion was <3 mg/dl had lower reticulocyte counts than fetuses whose umbilical venous total bilirubin was ≥3 mg/dl (10.5% ± 4.2% vs 24.7% ± 12.6%, $p = 0.0003$).

We previously described four hematologic patterns predicting the severity of fetal hemolytic disease on the basis of fetal hematocrit, direct Coombs test, and reticulocyte count.[1] These patterns were prospectively assigned to each of the 14 fetuses who had or developed an umbilical venous total bilirubin >3 mg/dl. Two fetuses were assigned pattern 1 (not at risk to develop severe anemia antenatally), three were pattern 2 (intermediate risk for anemia), and nine were pattern 3 (high risk). Each of three with pattern 2 and eight of the nine (89%) with pattern 3 developed severe hemolytic anemia. Of the remaining three fetuses, two experienced significant hyperbilirubinemia postnatally (as noted in the above paragraph). One of those two fetuses had been assigned pattern 1 and the other pattern 3.

Comment

We have examined the effect of gestational age and fetal hemolytic disease on the concentration of umbilical venous bilirubin. Normal fetal umbilical venous total and direct bilirubin (not shown) rose similarly with advancing gestational age. On the basis of the scattergram, it is likely that with a larger sample size we would have also observed a rise in the indirect bilirubin concentration. Although the number of measurements performed on specimens from the umbilical artery was inadequate to assess placental clearance of bilirubin di-

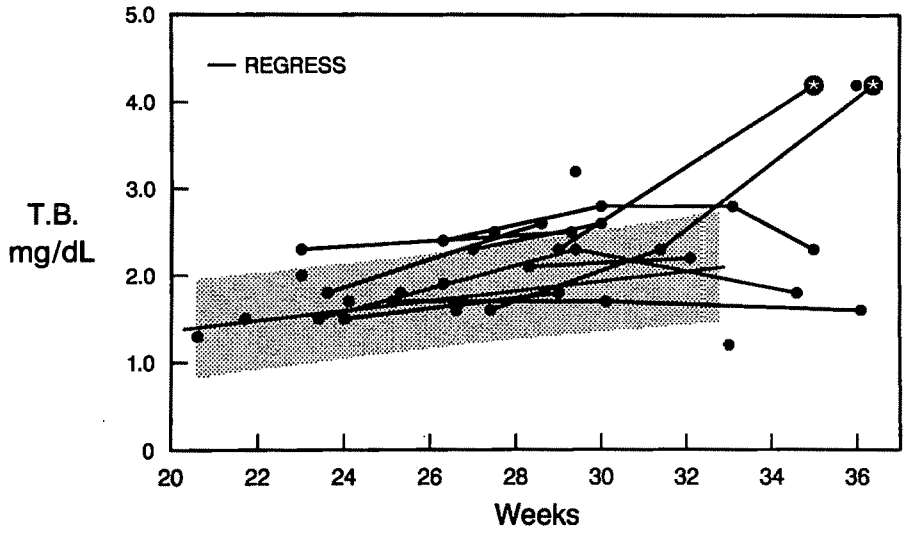

Fig. 5. Serial umbilical venous total bilirubin *(T.B.)* measurements of fetuses whose hematocrit remained above 30%. *Shaded area* indicates 95% prediction interval for normal umbilical venous total bilirubin. The two fetuses marked by *asterisk* developed significant postnatal hyperbilirubinemia.

rectly, the observation that normal neonatal bilirubin is much lower[2] than that of the near-term fetus suggests that placental capacity to transport the normal production of fetal bilirubin to the mother is relatively low.

Moise et al.[5] reported a single alloimmunized fetus whose serum was icteric and speculated that it reflected hemolysis.[5] In antigen-positive fetuses, there was an inverse relationship between hemoglobin and bilirubin independent of gestational age. The high concentration of bilirubin in the sera of antigen-positive fetuses was not likely secondary to decreased placental clearance because there was a significant inverse correlation between fetal hemoglobin and bilirubin in the antigen-positive group that was absent in the control group. This suggests that the greater the quantity of red blood cell hemolysis, the lower the hemoglobin.

The use of fetal blood instead of amniotic fluid for the evaluation of maternal red cell alloimmunization is a new concept not yet widely accepted. This unit has previously demonstrated that the antigen-positive fetus at risk for the development of severe hemolytic anemia can be prospectively identified on the basis measurements of fetal hematocrit, reticulocyte count, and strength of the direct Coombs test.[1] On the basis of these three tests, the antigen-positive fetus can be assigned to one of four hematologic risk patterns. The higher the pattern number, the greater the risk of the fetus developing a hematocrit <30%. The current investigation suggests that the addition of umbilical venous total bilirubin measurement to that battery of tests may be of value, especially in instances where the assigned pattern suggests the fetus is at no or low risk for the development of severe hemolytic anemia before birth. In our experience, only one of five fetuses with pattern 2 will become severely anemic antenatally. In the current series each of the three fetuses with both pattern 2 and an umbilical venous total bilirubin level >3 mg/dl developed severe hemolytic anemia. And although no fetus with both pattern 1 and an umbilical venous total bilirubin level >3 mg/dl developed severe anemia, one of the two did require 10 days of phototherapy postnatally.

Not all fetuses who became anemic had a high bilirubin level. This may reflect, in part, variability of placental bilirubin transport. However, there is an additional explanation. We have previously demonstrated that a sizable group of antigen-positive fetuses who become anemic do so gradually in association with a low reticulocyte count and a weakly positive direct Coombs test.[1] In the current investigation, fetuses whose umbilical venous total bilirubin level was <3 mg/dl before transfusion had significantly lower reticulocyte counts than fetuses whose level was ≥3 mg/dl. This suggests that the degree of hemolysis in some anemic fetuses is relatively low but that they fail to respond to red blood cell destruction with an adequate erythropoietic response. This observation would also explain why the amniotic fluid Δ optical density 450 of anemic fetuses is not always elevated.

In conclusion, the ability of the human placenta to clear fetal bilirubin is limited. Because of this limitation, fetal hemolytic disease is associated with fetal hyperbilirubinemia. The higher the bilirubin concentration, the lower the hemoglobin concentration. An elevated

fetal serum bilirubin indicates that the fetus is at high risk to develop severe hemolytic anemia antenatally. It may also provide additional information regarding the risk of postnatal hyperbilirubinemia.

Göttingen, Martinsried, Munich, and Bielefeld, Germany, and Debrecen, Hungary

Cervical biopsy specimens were obtained under standard conditions from the posterior lip of the uterine cervix in 105 patients. A significant increase of collagenase activity was observed during parturition as determined with an assay with iodine 125–labeled native triple-helical collagen type I as the substrate. The collagenase was not likely to originate from cervical fibroblasts because in situ hybridization failed to detect synthesis of the specific procollagenase messenger ribonucleic acid. However, migration of polymorphonuclear leukocytes into the cervical stroma occurred on onset of labor, and an antibody specific for human leukocyte collagenase that did not cross react with fibroblast collagenase revealed the presence of the enzyme in the granules of polymorphonuclear leukocytes and subsequently in the extracellular matrix of the cervix. Therefore it is likely that the cells critically involved in collagen degradation during cervical dilatation are not resident fibroblasts but rather polymorphonuclear leukocytes emigrating from blood vessels. (Am J Obstet Gynecol 1992;166:1455-60.)

Key words: Pregnancy, cervix, cervical dilatation, parturition, collagenase

A significant drop of hydroxyproline concentration in the cervix at the end of pregnancy has been frequently described[1-4] and attributed to increased collagenolysis, especially during childbirth.[5-7] However, no serial determinations of collagenase activity have been carried out in the cervix during childbirth. Kitamura et al.[8] found evidence for increased collagenolysis at the time of delivery compared with cervix samples from nonpregnant women. Ito et al.[9] determined the activity of a PZ-peptidase (4-phenylazobenzyloxycarbonyl-Pro-Leu-Gly-Pro-D-Arg) that may play a role in collagen degradation and found a marked increase in its concentration during pregnancy. All of these investigations must be viewed cirtically because small peptides were used as substrates to measure collagenolytic activity. Rath et al.[10] quantified the true collagenase activity by using native, triple-helical collagen as a substrate. The highest activity was measured immediately after parturition. No differences in collagenase and other protease activities were detected between samples from pregnant women during the first trimester and from nonpregnant patients. In the current study sequential examination of true collagenase activity at various times during the course of pregnancy and, in particular, during delivery was carried out. The source of cervical collagenase, which had not been previously determined, was also examined. Fibroblasts in many types of tissue are, of course, capable of synthesizing collagenase, but there are indications that other cell types, e.g., polymorphonuclear leukocytes, may be critically involved in the process of cervical dilatation during parturition.[11]

The aim of the current study was to establish the time course of the appearance of active collagenase in the cervix during parturition and to determine its cellular origin.

Material and methods

The design of the study was submitted to the appropriate ethics committees and accepted. Patients were informed in detail about the aims and the procedures of the study and gave their written consent. Cervical biopsies were performed under standardized conditions at various times during pregnancy and in nonpregnant patients by excising tissue with a scalpel from the posterior lip of the cervix at the 6 o'clock position to a depth of 5 to 10 mm. Samples of 50 to 200 mg wet weight were obtained. For the determination of collagenase activity and for in situ hybridization the tissue was deepithelialized, washed in ice-cold sterile saline solution, and deep frozen within 2 to 3 minutes in liquid nitrogen. The specimens were stored at −70° C in polypropylene tubes (Nunc) wrapped in aluminum foil until further examination. A total of 49 samples was available for collagenase extraction or in situ hybridization (Table I). An additional 115 specimens were procured under the same conditions for immunohistologic studies. They came from nonpreg-

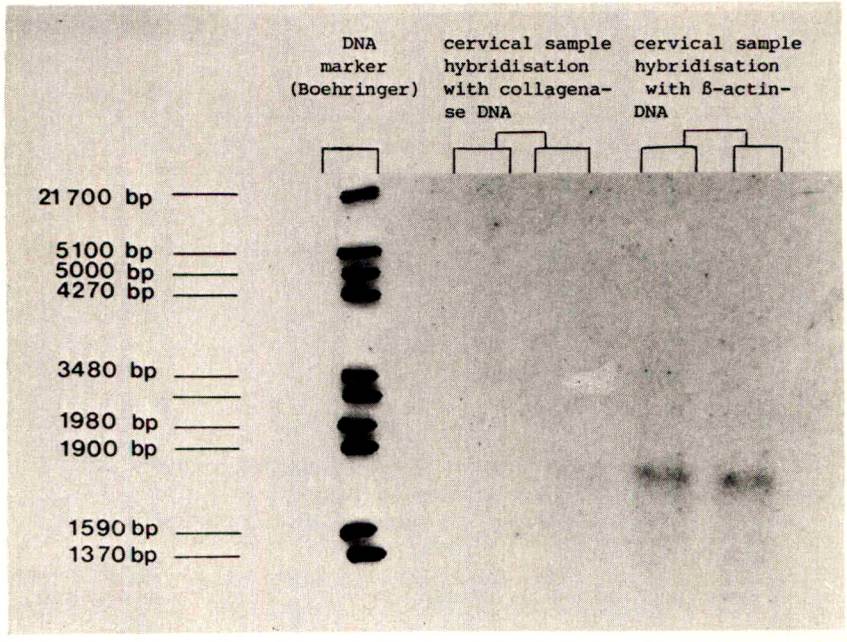

Fig. 1. Northern blot of mRNA extracted from cervical tissue and hybridized to phosphorus 35–nick translated complementary deoxyribonucleic acid *(DNA)* of β-actin or human fibroblast collagenase. Positive signal was obtained with probe for β-actin but not with that for collagenase, regardless of kind of cervix tissue.

Table I. Collagenase activity in extracts of cervical tissue

Origin of specimen	*No.*	*Collagenase activity*		*Significance (Wilcoxon–Mann-Whitney test)*
		Median ± SEM	*Range*	
Nonpregnant, premenopause	9	25.4 ± 1.4	12.4-31.7	
First trimester	10	26.3 ± 2.4	19.1-44.4	
Third trimester (no labor)	4	28.6 ± 3.8	14.7-31.6	$p < 0.05$
Latent phase of labor (cervical dilatation 2-3 cm)	5	27.0 ± 9.3	13.2-63.4	$p < 0.01$
Active phase of labor (cervical dilatation 6-8 cm)	8	40.0 ± 4.6	30.4-62.3	
Immediately post partum	13	29.1 ± 4.7	15.2-67.6	

Data represent nanograms of collagen degraded by the extract of 100 mg (wet weight) tissue.

nant, premenopausal patients (n = 20) and from pregnant patients during the first trimester (n = 20), during the third trimester (before elective cesarean section, no labor, unripe cervix; n = 15), in the latent phase of labor (cervical dilatation 2 to 3 cm, normal delivery; n = 15), in the active phase of labor (cervical dilatation 6 to 8 cm, normal delivery; n = 15), and immediately after delivery (n = 30). These tissues were not deepithelialized but were washed in ice-cold saline solution. They were then fixed in acid formalin and embedded in paraffin.

Active collagenase was extracted with neutral buffer and then assayed with native, triple iodine 125–labeled collagen as substrate.[10] In situ hybridization was carried out exactly as described by Scharffetter et al.[12]

The original clone (designated Coll K4) for human fibroblast collagenase was kindly donated by P. Herrlich, Karlsruhe, Germany. It was subcloned in a GEM3 vector (GEM3 plasmid, 2867 kb, Promega, Madison, Wis.). The plasmid GEM3 Coll K4 was cleaved by *Ava* I and *Hin*dIII (Boehringer Mannheim, Mannheim, Germany) and the linearized plasmids were purified by sodium acetate precipitation and phenol-chloroform extractions. Antisense and sense ribonucleic acid (RNA)

probes were obtained with sulfur 35–uridine 5′-triphosphate and by incubating the GEM3 Coll K4 *Ava* I vector with SP6 RNA polymerase and the GEM3 Coll K4 *Hin*dIII vector with T7 RNA polymerase, respectively. Total RNA was extracted from some cervix tissues by the isothiocyanate method of Davis et al.[13] and hybridized in Northern blots to nick translated deoxyribonucleic acid for β-actin or human fibroblast collagenase (matrix metalloproteinase 1). Normal dermal fibroblasts were grown in Dulbecco's minimal essential medium containing 10% fetal calf serum and exposed to 25 ng/ml tumor necrosis factor-α for 18 hours. Messenger RNA (mRNA) extracted from these cells was hybridized in Northern blots to ^{35}S-labeled antisense and sense RNA for β-actin or human fibroblast procollagenase. For immunofluorescence studies the tissue in paraffin was sectioned and paraffin was removed by passage through descending alcohol concentrations. The sections were rinsed in water or phosphate-buffered saline solution, followed by incubation with the immunoglobulin G fraction of an antiserum to human leukocyte collagenase. This antibody had previously been characterized and shown to react with human leukocyte collagenase but not with human fibroblast collagenase.[14, 15] The sections were incubated with this antibody at room temperature for 2 hours, rinsed extensively with phosphate-buffered saline solution, and stained with a fluorescein isothiocyanate–conjugated monoclonal antibody to rabbit immunoglobulin G in the dark for 2 hours at room temperature. After careful washing, the sections were embedded in glycerol–phosphate-buffered saline solution and immediately evaluated. We used the Wilcoxon–Mann-Whitney test for comparison of results, and the level of significance was set at $p \leq 0.05$.

Results

Cervical softening during parturition is likely to involve breakdown of collagens, which, in turn, requires the presence of specific collagenases. We therefore attempted to directly demonstrate such enzyme activity in cervical tissues during delivery and from controls. Biopsy specimens from a total of nine nonpregnant and 40 pregnant patients could be evaluated. Samples were available from pregnant patients in the first and third trimesters, during two stages of cervical dilatation, and immediately post partum. Active collagenase could be extracted from all specimens (Table I). There was great variation between individual samples and no statistically significant difference of the medians of collagenase activities between biopsy specimens from nonpregnant patients, patients in the first or third trimester (without labor), and in the latent phase of labor with early stages of cervical dilatation. However, collagenase activity rose substantially and significantly ($p < 0.01$) in the final stage of dilatation (6 to 8 cm) compared with the first trimester and dropped immediately post partum.

Although the presence of active collagenase was thus established, the source of the enzyme has yet to be determined. It may originate in the cervical tissue, either from resident fibroblasts or from migratory polymorphonuclear leukocytes. Fibroblasts would be expected to synthesize the enzyme in situ, whereas polymorphonuclear leukocytes are known to have granules that contain collagenase along with other proteases. The activity of fibroblasts can be evaluated by examining the production of specific mRNA for fibroblast collagenase, whereas the collagenase from polymorphonuclear leukocytes is best demonstrated by a specific antibody.

Our results with in situ hybridization did not demonstrate the presence of a messenger for fibroblast collagenase. This could not be attributed to method inadequacies for the following reasons: RNA extracted from the tissue reacted in Northern blots with a complementary deoxyribonucleic acid for β-actin (Fig. 1). This shows that RNA in the specimens was largely intact and had not been destroyed by the extraction procedure. Also, RNA extracted from tumor necrosis factor-α–stimulated fibroblasts reacted in Northern blots with the specific ^{35}S-labeled antisense RNA probe (not shown). There appears to be a genuine lack of collagenase messenger activity in cervical fibroblasts during cervical dilatation, and therefore the collagenase extractable from the tissue is not likely to originate from these cells.

Polymorphonuclear leukocytes are known to contain collagenase, among other vesicular enzymes, and are thus probably the source of the cervical collagenase. Collagenase was indeed easily detected as granular fluorescence within polymorphonuclear leukocytes in specimens from nonpregnant patients and from pregnant women during the first and third trimesters. At the end of pregnancy and at the onset of labor there was accumulation of polymorphonuclear leukocytes in the capillaries and small veins (Fig. 2). Massive leukocyte infiltration of cervical connective tissue occurred at the onset of labor and at the beginning of cervical dilatation (Fig. 3). At later stages there was degranulation of the polymorphonuclear leukocytes; the granules contained and later shed collagenase (Fig. 3). Finally, there was a weak fluorescent staining of the collagen fibers (Fig. 4).

Comment

The uterine cervix derives its tensile strength and firmness from collagen, which is the predominant protein of the extracellular matrix of this tissue. Therefore

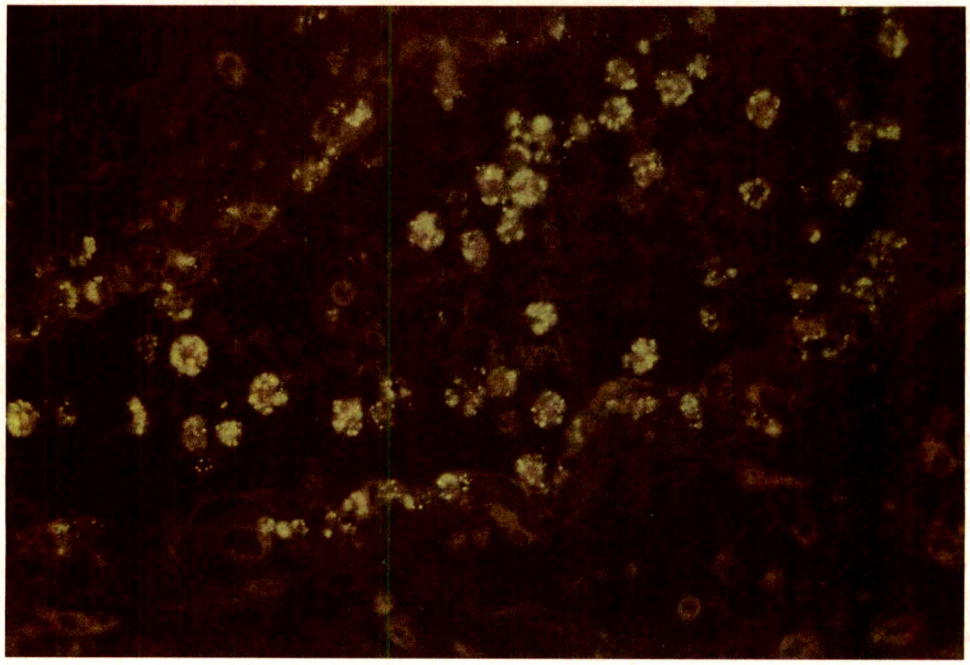

Fig. 2. Demonstration of leukocyte collagenase in cervical tissue by immunofluorescence, in third trimester without labor. Massive accumulation of polymorphonuclear leukocytes in small vein at end of pregnancy. (Original magnification ×630.)

alterations in these biophysical parameters during labor and cervical dilatation are likely to involve changes of the organization of the collagen fibrils. Early experiments by von Maillot and Zimmermann[4] and by Kleissl et al.[16] have demonstrated changes in solubility of collagen during cervical dilatation and a decrease of hydroxyproline concentration of the cervix during parturition. These data have been confirmed and extended by several investigators[4, 17, 18] and correlate well with histologic observations that show rarification of colla-

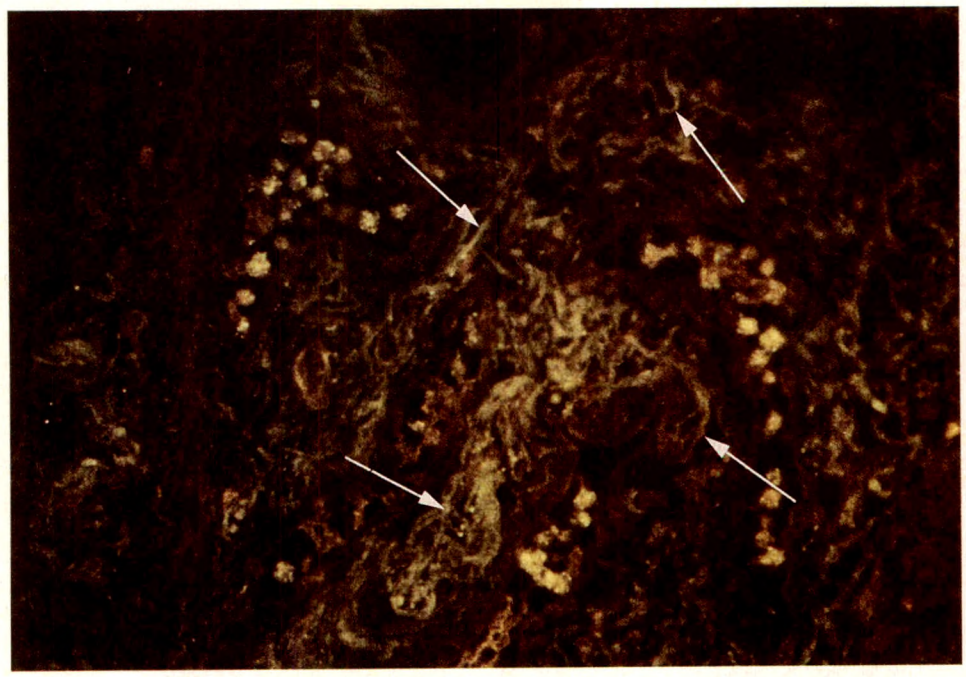

Fig. 4. Demonstration of leukocyte collagenase in cervical tissue by immunofluorescence, in active phase of labor, with cervical dilatation 6 to 8 cm. Some polymorphonuclear leukocytes are still visible within veins and capillaries, but in these late stages of labor there is additional faint staining of collagen fibrils *(white arrows)*. (Original magnification ×400.)

gen fibrils during labor by both light and electron microscopy.[11, 19]

Solubilization and degradation of collagen require attack by collagenase as the initial step. Cervical collagenase has been isolated[20] and increased collagenolytic activity has been demonstrated immediately post partum in humans[18] but not in some other species such as the guinea pig.[19] The current investigation provides data for the presence of active collagenase during pregnancy and labor. Other proteases are known to be present in the extracts of cervical tissue. These enzymes are not likely to interfere with the collagenase assay because the collagen was resistant to at least a tenfold excess of trypsin over substrate (unpublished data). The assay probably underestimated the amount of collagenase protein present in the cervical tissue because some of the enzyme may not be activated, may be inhibited, or may not have been extractable. The experiments were designed to determine the time of appearance of active collagenase in the tissue and thus the time of collagen breakdown. The data establish that maximal activity occurs transiently immediately before parturition.

It has to be emphasized that no conclusion can be drawn from our findings that the increase of collagenase activity occurs exclusively during the active phase of labor. Indeed, there is no significant increase during the active phase as compared with the latent phase of labor. The quite wide ranges in the latent phase are grounds for the assumption that the increase of collagenase activity in cervical tissue occurs much earlier, presumably with the onset of labor.

The source of cervical collagenase was then determined. Because fibroblasts and smooth muscle cells are known to be capable of producing collagenase, it was assumed that these cervical cells were the source of the enzyme during labor.[21, 22] The availability of two crucial reagents permitted us to study this issue in some detail. Because cells of the fibroblast type do not store collagenase but rather synthesize the enzyme on activation, it was possible to use a specific probe to study the expression of the corresponding mRNA during labor. However, this messenger mRNA could not be found in the cervical sections examined. Because this cannot be attributed to method inadequacies, it must be concluded that fibroblast cells are not likely to contribute a major portion of the collagenase observed. The conspicuous presence of polymorphonuclear leukocytes in the extravasal matrix of cervical connective tissue during parturition had already led Junqueira et al.[11] to surmise a connection between these cells and the process of cervical softening. Our investigation of the involvement of polymorphonuclear leukocytes was facilitated by the availability of a well-characterized antibody that had been shown[14] to react with leukocyte collagenase but not with fibroblast collagenase. The immunofluorescence data clearly demonstrated, concomitant with progressive cervical dilatation, that an accumulation of collagenase-containing leukocytes in

small vessels occurs, followed by an extravasation of these cells, degranulation and release of collagenase protein, and finally degranulation of collagen fibrils of the extracellular connective tissue matrix. Although this experimental approach can only demonstrate the presence of the enzyme protein and does not yield information on its enzymatic activity, it appears likely that this is indeed the enzyme that causes collagen breakdown during normal cervical dilatation. Further studies are required to elucidate the trigger mechanisms that cause accumulation, extravasation, and degranulation of polymorphonuclear leukocytes under these circumstances.

We thank Mrs. Cornelia Platte for technical assistance.

Acute genital injury in the prepubertal girl

Susan F. Pokorny, MD, William J. Pokorny, MD,[b] and Wayne Kramer, MD[a]

Houston, Texas

In an effort to develop guidelines for the management of acute genital injuries in prepubertal girls, we categorized 32 cases by the object that allegedly caused the injury: straddle injuries, nonpenetrating injuries, penetrating injuries, and torque injuries. Using these categories and the anatomic features of symmetry and/or hymenal transection, we determined that the most dangerous injuries were the penetrating injuries that were symmetric and transected the hymen; in this series these were all the result of sexual assault. Future studies are needed to determine if these unique injuries can be managed with less physical and psychosocial trauma to the young patient. (Am J Obstet Gynecol 1992;166:1461-6.)

Key words: Genital injury, prepubertal girls, sexual abuse

Genital trauma in the prepubertal girl is often relatively minor, but it is frequently anxiety provoking to all involved individuals. With increased public and physician awareness of childhood sexual abuse, surgical specialists are more frequently being called on to assist in the management of these injuries.[1] Unfortunately there are no published guidelines on how to evaluate and/or manage genital injuries in girls. Most authors describing perineal injuries in children have confined their remarks to serious external genital injuries of the male child and/or impalement injuries.[2-4]

A retrospective review of 32 prepubertal girls with acute genital trauma was undertaken. The purposes of this case study are to bring to the surgical consultants' attention the psychosocial issues that are involved with these injuries and to establish guidelines for their care. Parents or primary care providers are frequently concerned as to whether sexual abuse has occurred. Certainly the process of evaluation and management of the wound can contribute to further physical and emotional trauma for the abused patient. Guidelines are developed that incorporate aspects of the history and characteristics of the wound and address the following issues: Were the viscera above the external genitalia likely to be injured? Could the wound be managed conservatively, or should the child be taken to the operating room for an examination while she is under anesthesia? Did the history given correlate with the type of wound observed?

Methods and material

Thirty-two children with primary external injuries confined to the perineum were studied. The injuries caused acute bleeding and/or a painful outcry to the extent that the child was brought for emergency care. Patients whose bleeding was attributed to a genital pathophysiologic process other than trauma were excluded. Children whose primary presenting injury involved another area of the body yet who had a secondary genital wound were also excluded. Two children (cases 27 and 28) denied injury in spite of perineal bleeding and the presence of perivaginal lacerations and/or abrasions. They were placed in the penetrating category because their denial of trauma in light of gross wounds signaled the possibility of sexual abuse. Because estrogen thickens and increases the distensibility of vulvar tissues, only children ≤10 years old were included and none had entered puberty; the mean age was 6.33 years.

Demographic, historic, evaluation, management, anatomic, and follow-up data were gathered from the medical records (Table I). All of these children were examined by one author (S.F.P.), and 21 had photographs available for review.

Injuries were categorized by definition of the object that allegedly caused the injury. Straddle injuries were defined as falls onto smooth, horizontal, elongated narrow objects such as bicycle bars. Nonpenetrating injuries were caused by falls onto short, wide, and frequently irregular objects that were unlikely to penetrate above the pelvic floor. Penetrating injuries were associated with objects long and narrow enough to penetrate the pelvic floor; no stab or gunshot wounds were included. Torque injuries were complex injuries of the perineum caused by crush and torsion of the pelvic floor.

In an attempt to ascertain whether certain types of injuries should make the clinician suspicious of sexual

*Children seen initially in other emergency centers and referred to S.F.P. for further and/or follow-up care.

abuse, the data were analyzed by comparing the anatomic findings with both the cause of the injury and the history. The Fisher exact test was used to test differences between proportions, and the Student *t* test was used to test differences between two means.

Results

The majority of these children were seen in the emergency center at Texas Children's Hospital, a referral children's hospital. The ethnic background of the subjects reflected the general population served: blacks, 40% ($n = 13$); whites, 31% ($n = 10$), and Hispanics, 28% ($n = 9$). Four children were initially managed at another facility and referred for follow-up care (cases 10, 16, 20, and 29); Two of these children received sutures for relatively minor superficial wounds that did not transect the hymen, and two others had transections of the hymen but did not undergo an examination under anesthesia.

Children's Protective Services or the police were involved with 15 patients: eight solely because of the genital location of the injury, five because of the child's allegations of sexual abuse, and two (cases 27 and 28) because of other concerns about abuse. In case 27 the patient denied any type of injury in spite of a fresh laceration extending from the posterior forchette into the vagina through an extremely attenuated hymen, suggesting both acute and chronic penetration (Fig. 1). In case 28 the patient was a retarded girl who, in addition to the acute genital injuries, had gonorrhea cultured from the vagina.

To determine if the eight children with no substantiation of abuse other than the genital injury were referred for investigation of childhood sexual abuse because they were younger (less verbal) and/or because of emergency room personnel bias, which would lead them to suspect sexual abuse in certain ethnic subsets, the age and race of these eight girls were analyzed.

These children were younger, with a mean age of 5.1 years versus 6.33 years for the group as a whole, and seven of the eight were of a minority background. Nevertheless, with the Student *t* test there was no statistical difference of age or of the racial distribution of these patients other than the racial distribution of the injury category from which that case originated. There was a trend for minority children to undergo more investigations for sexual abuse than white children.

The objects that allegedly caused the injuries are listed in Table I. The two torque injuries involved motor vehicles. The patient in case 31 was 2 years 9 months old and was thrown from a motorcycle. In case 32 the patient was a 3-year-old girl who was crushed between a building and a car; she sustained six fractures of the pelvis and a massive ischiorectal hematoma that dissected into the retroperitoneal space before rupturing through the vestibule and creating a massive perineal laceration.

The anatomic variables that were analyzed were the following (Fig. 2): (1) Was the wound symmetric or asymmetric? (2) Was the hymen transected? (3) Was the wound confined to the external genitalia? (4) Was the wound relatively minor or was it severe?

There were 16 symmetric and 16 asymmetric lesions. When a symmetric injury transected the hymen, there was a very strong possibility that the injury was caused by sexual abuse (seven out of 10 patients). Because of this association, symmetric injuries and ones that transected the hymen were analyzed in more detail.

Four of nine straddle injuries were symmetric, but none of them transected the hymen. Four of the 13 nonpenetrating injuries were symmetric, and three of these transected the hymen. These three wounds apparently were "direct hits": In case 12 the patient slid down a tree trunk onto a protruding irregular stump (Fig. 3); in case 15 the patient was being evaluated to rule out rectal bleeding when the emergency room physician's gloved finger inadvertently entered the vagina of the girl; in case 18 the patient jumped into a wading pool and landed on a plastic toy.

None of the three symmetric nonpenetrating injuries that transected the hymen acutely widened the vaginal introitus (Fig. 3), and the apex of the laceration was visible in the lower aspect of the vagina. The seven patients with symmetric penetrating injuries caused by rape all had a widened vaginal introital diameter (Figs. 1 and 4) when they were seen in the emergency center. In three of these injuries (cases 24, 27, and 28) attenuation of the hymenal tissue contributed to the widened diameter (Fig. 1).

In 16 children in whom the cause of the injury was known to be either a straddle or a nonpenetrating object (16/22) and who were hemodynamically stable, initial emergency room management consisted of reassurance, keeping her quiet and supine, and applying ice packs and a pressure dressing to the perineum. This ultimately resulted in decreased swelling and pain and gained the child's cooperation so that the wound and perineum could be copiously lavaged. It was then possible to determine the full extent of injury without a need for anesthesia.

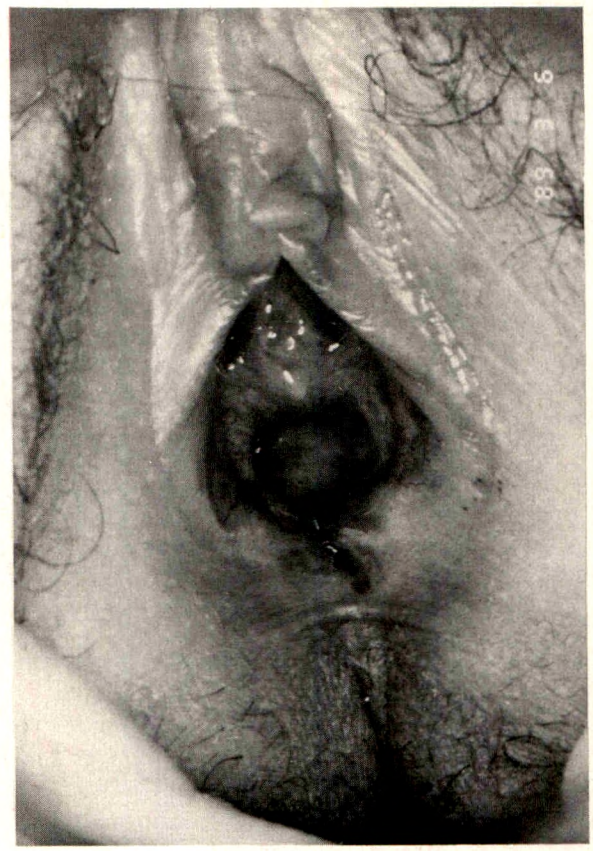

Fig. 1. In case 27 the patient was 8 years old with profuse vaginal bleeding, adamant denial of injury, and multiple social risk factors for abuse. Note attenuation of posterior hymenal tissue which is suggestive of chronic penetration.

Six of the 22 patients in whom the cause of injury was known to be either a straddle or a nonpenetrating object required an examination while they were under anesthesia. These six children were younger than the group as a whole, but there was not a statistical difference in their ages when the Student *t* test was used. They also remained uncooperative and had very hemorrhagic wounds (cases 1, 4, 5, 10, 17, and 20). The wounds were ultimately found to be relatively minor, requiring simple cauterization of a bleeder in three cases, placement of one suture in two, and approximation of a partially severed perineal body in one.

The most serious injuries in this series were three rape survivors (cases 23, 26, and 30), one accidental impalement (case 25), and two motor vehicle accident victims (cases 31 and 32). In all six of these girls an extensive injury was suggested preoperatively. The wound extended either into the upper vagina or into

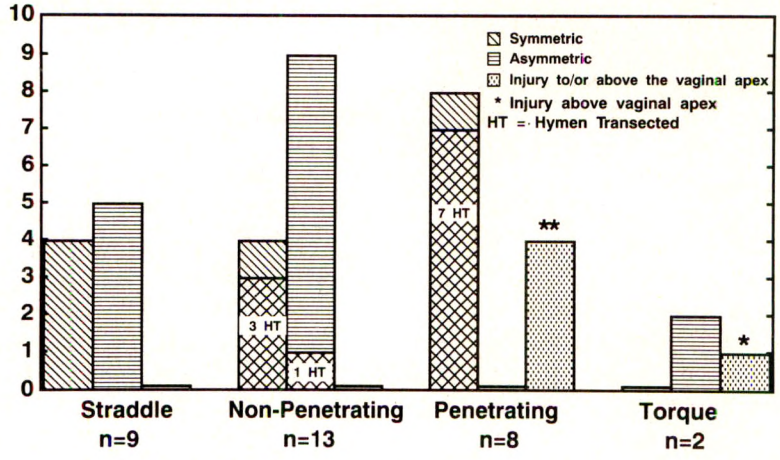

Fig. 2. Anatomic variables by cause of injury. *Bars* indicate whether wound was symmetric *(first bar)* or asymmetric *(second bar)* and whether injury extended to/or above vaginal apex *(third bar)*; three injuries *(asterisk)* extended above vaginal apex, and 11 injuries included hymenal transection *(HT)*.

the perineal tissues beyond what could be visualized by an external examination.

In three of these patients there was injury above the vaginal apex: In case 25 there was perforation of the rectum, cul-de-sac, and small bowel in multiple sites; in case 26 a vaginal laceration extended through the cul-de-sac into the abdominal cavity; in case 32 a massive hematoma extended into the right retroperitoneal space.

None of the three children with injuries above the vaginal apex had signs of higher abdominal or pelvic injury when first seen in the emergency center. In cases 26 and 32 the patients had extensive visible perineal injuries and were taken for operative repair, at which time the higher, more extensive injuries were detected. One patient (case 25), who had severe visceral injuries, did not complain of abdominal pain until several hours after being admitted and observed for what was thought to be a superficial penetrating injury to the perineal body. She was taken to the operating room after an acute abdomen developed.

Diverting colostomies were performed in three cases. In cases 25 and 32 they were performed to maximize healing of bowel injuries and/or to diminish fecal soiling of the perineal injuries, which were debrided, drained, and allowed to close by secondary intent. In case 23 the patient underwent a colostomy in preparation for primary closure of a fourth-degree perineal body laceration that was 5 days old when first seen. All three had excellent anatomic results.

All three rape survivors in whom operative intervention was required had vestibular lacerations that extended through a distinct rim of hymenal tissue, high into the vagina along the vaginal wall. Two patients (cases 26 and 30) also had another extensive laceration in the apex of the vagina, which extended from one lateral vaginal fornix in a curvilinear fashion, posterior to the cervix, and into the opposite vaginal fornix; this laceration extended into the abdominal cavity in one patient (case 26).

No endoscopic studies were performed unless the child was under anesthesia. Vaginoscopy, with the pediatric cystoscope, was performed on six of the 12 children who required an anesthetic for evaluation of their wounds. Because the hymen was intact in case 25, that impalement injury was the only vaginal wound that was unexpectedly discovered. The three sexual assault survivors who had endoscopic studies performed had obvious vaginal injuries that did not require vaginoscopy for discovery.

In this series there was only one patient (case 32) in whom cystoscopy was performed; that child had pelvic fractures and suspected urethral injury. However, the pelvic fractures were not discovered until she underwent an examination while she was under anesthesia and a bladder catheter was already in place.

Proctoscopy was performed on two girls while they were under anesthesia: In case 25 a rectal perforation was identified just inside the rectal verge by digital examination, and no higher perforation was identified by proctoscopy; in case 32 there were no rectal or colon perforations.

Although large vaginal lacerations were closed primarily, very few of the perineal injuries reported in this series required primary closure and/or suturing for hemostasis. In the majority of cases requiring operative intervention the wound was debrided and allowed to close by secondary intent, particularly if it was a sagittal laceration confined to the mucosa.

When the perineal body was transected, it was pri-

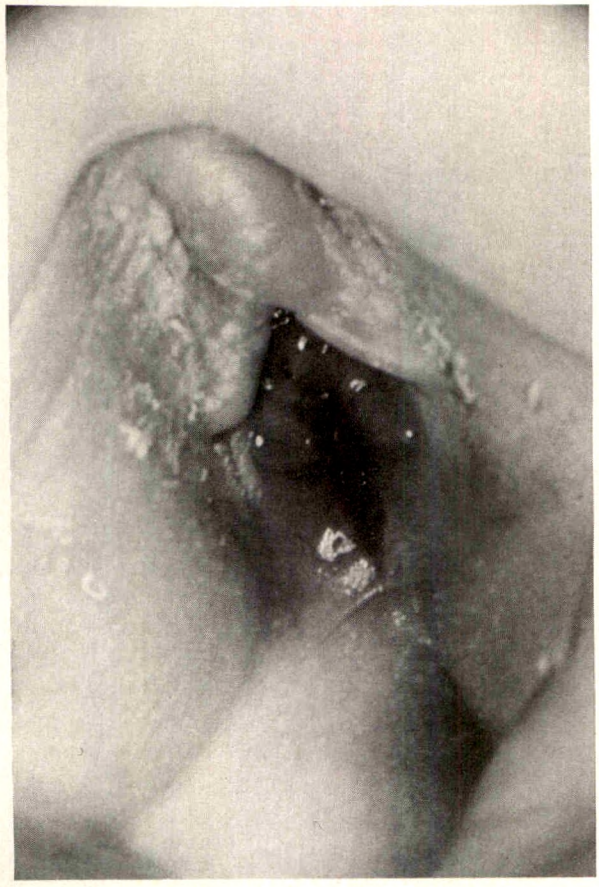

Fig. 3. In case 12 a 3-year-old girl slid down a tree trunk and lacerated the posterior fourchette, hymen, and 1 cm of the lower vagina on a smooth knuckle of tree stump.

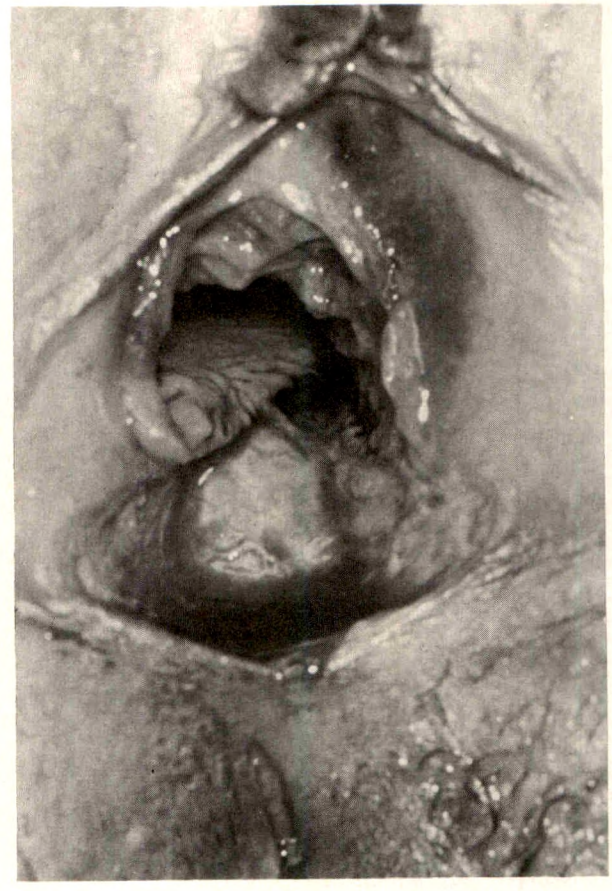

Fig. 4. In case 26 an 8-year-old girl was a survivor of stranger rape. She had avulsion of the vaginal apex with herniation of small bowel.

marily closed in two patients (cases 4 and 23) and allowed to close by secondary intent in three patients (cases 25, 31, and 32). The success in the latter three cases could be attributed to the fact that other injuries kept these children immobilized for a sufficient amount of time for secondary repair to occur.

Nineteen children were seen at follow-up 2 days to 3 years after the injury. There were no serious complications related to the injuries. In three a friable mass of granulation tissue developed at the site of the injury; when this tissue was in the lower vagina (cases 16 and 25), a short course of topical estrogen cream allowed these wounds to epithelialize, and the symptoms resolved. A small mound of perineal granulation tissue at the wound site was cauterized when one child (case 31) was under anesthesia for colostomy closure. Three of the four patients who had been raped had chronic vaginitis when seen at follow-up; none of these three had any remaining hymenal tissue.

Six girls who were noted initially to have transected hymens, two caused by nonpenetrating objects and four among the penetrating rape cases, were seen at follow-up. Injury had healed well in all six, although the transection of the hymen remained.

Comment

Although genital injury is relatively common, when it occurs in a prepubescent girl, it is very anxiety provoking to all involved individuals. Because of its genital location and the cognitive limitations in the young child, caretakers frequently are concerned about sexual abuse. In this small series eight of 25 children (32%) were investigated for sexual abuse, even though the children gave no history nor did they have other indicators of abuse, e.g., a sexually transmitted disease or denial of injury.

Another cause for alarm is that these wounds tend to be very hemorrhagic. The external genitalia are very heavily vascularized, and a relatively minor injury can bleed excessively, particularly on the unestrogenized mucosa. The vast majority of the injuries reported here were managed conservatively in the emergency center after a history seeking the cause of the injury was obtained. However, several of the youngest and more un-

cooperative patients in this series were taken to the operative room for examination and repair of relatively minor but hemorrhagic wounds.

The anatomic feature most commonly associated with a serious wound was symmetry, which is an indication that the force of the injury was in the midline. A symmetric wound combined with hymenal transection indicates that the weakest point in the perineal floor has received the force of the causative agent. When one is dealing with injuries, other than those caused by stabs or gunshots, it is through this point in the pelvic floor that injury to internal pelvic and abdominal structures is possible.

The one group of symmetric injuries that, although painful, had minimal potential for penetration of higher viscera were caused by straddle objects; the hymen remained intact in all nine of these patients. Straddle object injuries have the potential for urethral injury and large hematoma formation, although neither of these occurred in this series.[5]

When the hymen was transected in association with a symmetric wound, not only was the potential for damage to higher viscera increased but also there was a much greater association with sexual assault. In this series deep penetrating injuries that were symmetric and transected the hymen were uniformly the result of sexual assault. It must be emphasized that the injuries caused by rape were distinctly different than the three injuries caused by nonpenetrating objects, which were also symmetric and transected the hymen. In the sexual assault survivors the vaginal introitus was clearly enlarged, and either there was a major laceration of the tissues (acute rape) (Fig. 4) or the hymen was markedly attenuated (chronic sexual abuse with acute penetration) (Fig. 1). The vaginal introitus was not widened in the acute, nonpenetrating injuries with symmetry and hymenal transections (Fig. 3).

Instrumentation of the vagina was not uniformly required and was reserved only for examinations with the patient under anesthesia. The pediatric cystoscope is an ideal instrument to examine the vagina of the prepubertal girl. Any speculum regardless of size will damage the hymen, and possibly the atrophic vaginal mucosa, and can rarely be opened sufficiently to examine the entire vagina. The small 5 mm diameter of the pediatric cystoscope will not damage the hymen, and the irrigating fluid will cleanse and expand the vaginal canal. The labia can be gently squeezed closed around the cystoscope to retain fluid and further expand the canal.

At some point attention must be given to the child's ability to urinate. Viscous lidocaine applied to the tender periurethral tissues and/or sitz baths will relieve the discomfort and spasm and allow the child to micturate. In this series no child was catheterized in the emergency center. If urethral injury is suspected, catheterization should be delayed until cystoscopy has ruled out a complete or partial urethral transection.[4, 5]

Because the location of a perineal injury does not allow it to be bandaged or splinted, allowing a child to return to normal activities too soon can be detrimental. Quite and supine activities are necessary to prevent a small hematoma from expanding and to allow approximation of tissues for secondary healing to occur. Frequent tub or sitz baths are also an important part of wound management because the area has high fecal contamination.

With the exclusion of gunshot or knife stab wounds, we believe that management guidelines can be suggested for acute genital injuries in the prepubertal girl. First, the clinician should consider what type of object allegedly caused the injury and, second, determine if the anatomic features of symmetry and hymenal transection are present.

If the object is of the penetrating type, even if the child is having minimal bleeding and/or no apparent distress, the possibility of higher visceral injury is great, especially if associated with symmetry and hymenal transection.

On the other hand, if the object was too small or too wide to penetrate higher, even if the child is screaming and has soaked several peripads with blood, she might not require a trip to the operating room, especially if the injury is asymmetric and the hymen is intact. Reassurance and/or sedation to calm the child and a pressure dressing against the wound may result in hemostasis and a more conservative approach.

We would like to thank Dr. Claudia Kozinetz for statistical analysis of the data presented.

The use of a neural network for the ultrasonographic estimation of fetal weight in the macrosomic fetus

Richard M. Farmer, MD, PhD, Arnold L. Medearis, MD, Greigh I. Hirata, MD, and Lawrence D. Platt, MD

Los Angeles, California

The error associated with regression analysis methods for the ultrasonographic estimation of fetal weight in the suspected macrosomic fetus, approximately 10%, is clinically unacceptable. This study was undertaken to evaluate the applicability of an emerging technique, biologically simulated intelligence, to this problem. One hundred patients with suspected macrosomic fetuses underwent ultrasonographic measurements of biparietal diameter, head and abdominal circumference, femur length, abdominal subcutaneous tissue, and amniotic fluid index. The biologically simulated intelligence model included gestational age, fundal height, age, gravidity, and height. The model was then compared with results obtained from previously published formulas relying on the abdominal circumference and femur length. The biologically simulated intelligence yielded an average error of 4.7% from actual birth weight, statistically better ($p = 0.001$) than the results obtained from regression models. (Am J Obstet Gynecol 1992;166:1467-72.)

Key words: Ultrasonography, macrosomia, estimation of fetal weight, neural network, biologically simulated intelligence

Accurate estimation of fetal weight in the clinically suspected macrosomic fetus continues to be an area in evolution. Perinatal and maternal morbidity increases with larger birth weights,[1-3] making correct identification of the macrosomic infant essential. Once the fetus at risk has been identified, clinical decisions and precautions can be used to reduce morbidity.[4] Clinical estimation of fetal weight by means of the Leopold maneuvers has not been shown to be accurate.[5] Roentgenographic and computed tomographic examinations of the fetus have also not been useful, because the predictive value offers no advantage over ultrasonography and it has the concern of fetal roentgenographic exposure.[6] Ultrasonography continues to be considered the most reliable means of estimating fetal weight. Regression analysis of standard measured parameters generated in nonmacrosomic populations by Hadlock et al.[7] and Shepard et al.[8] has yielded the most common formulas for the estimation of fetal weight. Hirata et al.[9] found that Hadlock's model performs best in the macrosomic population, in spite of the fact that estimated fetal weights calculated from these formulas can vary from the actual birth weight by ≥10%. Using a study population of suspected macrosomic fetuses rather than the general population to generate regression curves has not yielded significantly better results.[10]

An emerging technique for data analysis is biologically simulated intelligence or neural network. The forte of the neural network is pattern recognition, which can be likened to regression analysis where input variables are associated with outcomes according to a specified relationship to obtain a predictive model. The actual data reduction is unique to the neural network, which is derived from models of the human pattern of thinking. The technique excels in correlating many variables that, when taken alone, may not be statistically significant but as a group provide added information to best model an outcome. This technique uses a nonlinear system of variable weighting to best model input data.

The purpose of the current study was to determine the applicability of a biologically simulated intelligence to the estimation of fetal weight in the clinically suspected macrosomic fetus. This model was then prospectively tested against the Hadlock and Shepard models.

Material and methods

The study population consisted of 102 patients seen at Los Angeles County–University of Southern California Women's Hospital, either in the clinic population

or in the labor and delivery suite, with a clinically suspected macrosomic fetus. Excluded from the study were the fetuses of women with diabetes, anomalous infants, multiple gestations, and women whose advanced labor precluded an accurate ultrasonographic examination. All ultrasonographic measurements were conducted within 72 hours of delivery. Measurements were made with an ATL Ultramark-4 (Bothell, Wash.), a GE RT 3000 or GE RT 3600 (Milwaukee, Wis.), or a Corometrics Aloka 620 (Wallingford, Conn.). All measurements were made with a 3.5 MHz linear array transducer.

The biparietal diameter, occipitofrontal diameter, transverse abdominal diameter, anteroposterior abdominal diameter, and femur length were measured with standard techniques. Circumferences of the head and abdomen were calculated with the equation for a circle: Circumference = (Diameter 1 + Diameter 2) · 1.57. An assessment of the subcutaneous tissue was made by measuring the distance from the bony spine to the skin in the anteroposterior orientation at the level of the abdominal circumference. The amniotic fluid index was measured as previously described.[11] Calculated values were the head circumference/abdominal circumference and the femur length/abdominal circumference ratios. The other measured variable was the fundal height, which was measured in centimeters from the symphysis pubis to the fundus. Demographic variables included in the analysis included gestational age, gravidity, parity, and height of the patient.

The biologically simulated intelligence used to model the data was the Brainmaker software package (version 1.5, California Scientific Software, Sierra Madre, Calif). The input variables were gestational age, fundal height, amniotic fluid index, biparietal diameter, head circumference, abdominal circumference, subcutaneous tissue measurement, femur length, head circumference/abdominal circumference, femur length/abdominal circumference, gravidity, parity, and patient height. Data used to develop the network were taken from a previously published set of 146 patients from this institution.[7] The model was then successively iterated until the estimated fetal weight (the output variable) agreed with the actual birth weight within specified tolerance. Adjustments with respect to the number of neurons, neuron gain, and training tolerance were made to obtain maximal performance on a training subset. Prospective evaluation of the trained network was then conducted on the 102 patients described above.

Data analysis was conducted on a personal computer–based system with the CRUNCH statistical software package (Crunch Software Corp., Oakland, Calif.). The error in the estimated fetal weight is expressed as a percentage of the actual birth weight[7] as follows: Error (%) = (Estimated fetal weight − Actual birth weight)/Actual birth weight × 100. An estimated fetal weight was calculated for each patient with the neural network model, the Hadlock formula, and the Shepard formula. The Hadlock estimated fetal weight was calculated with the model: Log_{10} estimated fetal weight = 1.304 + 0.05281(abdominal circumference) + 0.1938(femur length) − 0.004(abdominal circumference)(femur length). The Shepard estimated fetal weight was calculated from: Log_{10} estimated fetal weight = −1.7492 + 0.166(biparietal diameter) + 0.046(abdominal circumference) − [2.646(abdominal circumference)(biparietal diameter)]/1000. Paired *t* tests were used to compare the difference in the mean percent error derived from the Hadlock, Shepard, and neural network models. Significance was defined as $p < 0.05$.

Results

The average birth weight in the study population was 4250 ± 350 gm, with a range of 3360 to 5260 gm. Seventy of the 101 infants (69.3%) had a birth weight ≥4000 gm, whereas 24 (23.8%) weighed ≥4500 gm at birth. The distribution of actual fetal weights when there was a clinical suspicion of macrosomia is displayed graphically in Fig. 1. A total of 62.4% (63/101) infants were ≥41 weeks' gestation. There were no anomalies or neonatal deaths in the study population.

The mean error from the actual birth weight obtained with the neural network was 4.7% ± 3.9%, whereas the Shepard and Hadlock formulas' errors were 6.5% ± 4.6% and 6.8% ± 5.0%, respectively (Table I). The neural network results were calculated with the input variables outlined in Material and Methods. Another neural network was generated with only abdominal circumference and femur length used as input variables, with a resultant mean error of 6.1% ± 4.5%.

The performance of each model over the weight range studied is shown graphically in Fig. 2. The points shown are the mean percent deviation from the actual birth weight within the weight range specified.

Comment

The ultrasonographic estimation of fetal weight in the clinically suspected macrosomic fetus is an area that continues to evolve. Previous efforts in this area have focused on correlating a few morphometric parameters, i.e., the biparietal diameter, abdominal circumference, or femur length, with birth weight. However, the error associated with these methods has been imperfect. Because most of the permutations of these morphometric measurements have been explored, it might seem reasonable to postulate that inclusion of more parameters would add to the predictive value of a model. Although a given parameter, when taken alone, does not statistically contribute to a model, an aggregate of parameters related to macrosomia may

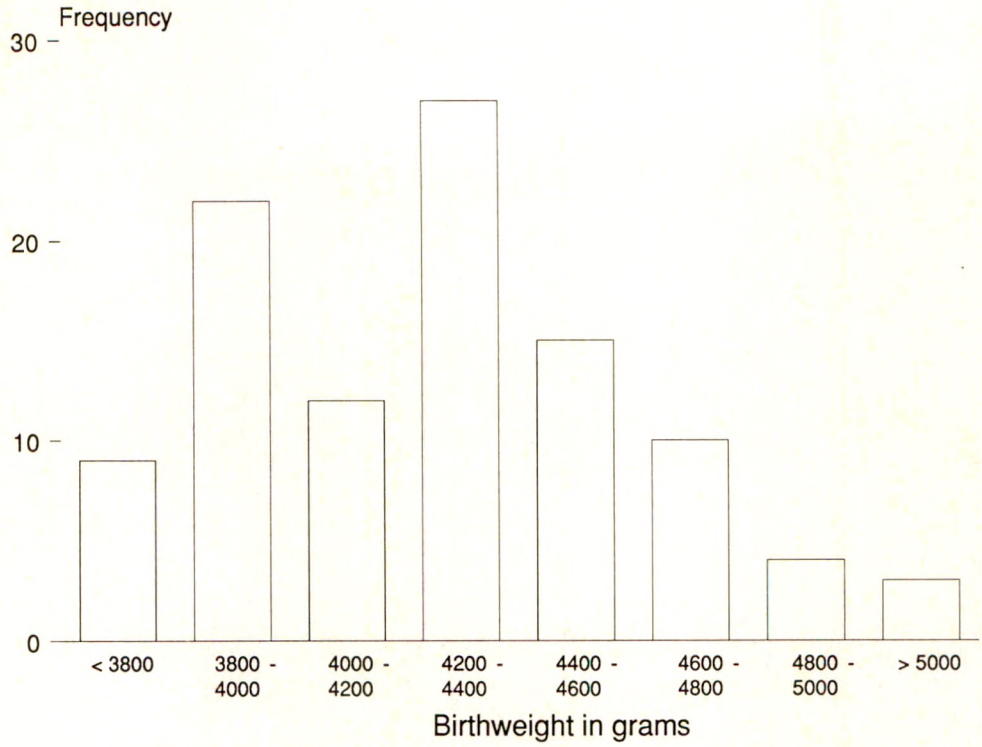

Fig. 1. Actual birth weight distribution in clinically suspected macrosomic infants.

round out a model so that its performance best predicts the actual birth weight. The problem with such an approach in the past has been the unwieldy nature of the data analysis with multiple parameters.

The analysis of multiple parameters to develop a predictive model is the forte of the neural network or biologically simulated intelligence. A neural network model was first used as a research tool to model human thinking. The computer sets up a miniature model that simulates the biologic architecture of the human brain, with the terminology of the network borrowed from neurobiology (Fig. 3). The biologically simulated intelligence relies on a training data set as input, with the number of variables corresponding to the number of input neurons. The input layer is then connected to a prespecified number of neurons in the hidden layer so that all inputs are connected to all neurons in the hidden layer. Similarly, all neurons of the hidden layer are connected to an output layer, the result(s) to be modeled. The training set, matched data and outcome, is then run through the network. The network then attempts to vary the interconnections between the input-hidden layers and the hidden-output layers until the specified outcome is obtained for each input. The process is iterative, with the entire data set run through the network numerous times until all inputs match all outputs. The model is then ready for use as a predictive tool.

The neural network model is statistically more accurate than the Hadlock or Shepard formula ($p < 0.05$). The standard deviation of the percent error is minimized with the neural network model, an indi-

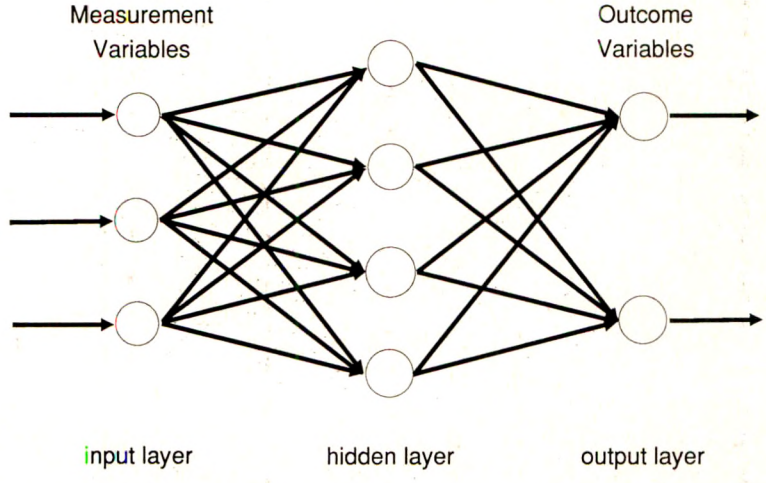

Fig. 3. Schematic representation of neural network architecture.

cation of the method's precision and accuracy. With the use of only the abdominal circumference and femur length the network model yielded results that were not statistically different from either the Hadlock and the Shepard model.

The performance of a model over the study weight range is shown in Fig. 2. It is of interest that all models have a diminished performance at the extremes of the weight range, especially when the birth weight is <3800 gm. A possible explanation for this may be operator bias on the basis of referral indication. A clinical suspicion of macrosomia existed for inclusion in the study. This clinical impression may have carried over into a bias in the measurement of morphometric parameters, particularly abdominal circumference. The result would be the systematic overestimation of fetal weight

when the actual birth weight was <3800 gm. All models would be expected to perform poorly because the data was biased before calculation of estimated fetal weight.

At the other end of the scale infants >4800 gm represent technical problems in the estimation of abdominal circumference because the entire abdomen may not fit on the display. This would result in estimations of abdominal circumference that would tend to favor the bias of the observer. In this study it resulted in a systematic bias toward underestimation of fetal weight in the larger weight ranges. The problems of bias exist for all the models studied. However, the underestimation of fetal weight for infants with a birth weight >4800 gm appears greater for the neural network model than for the regression models. A possible explanation for this lies in the method of data analysis particular to the neural network. The network relies on past experience with a subset of the range for accurate prediction. The model will deteriorate significantly when there are not enough data in a given area. In particular, there are only seven infants with birth weights >4800 gm. The model's predictive ability would probably be significantly enhanced by the inclusion of more infants in this weight category. Finding

such study candidates would be the major impediment to the improvement of the model in this weight range.

Exclusion of infants at the weight extremes of birth weights <3800 and >4800 gm results in the exclusion of 16 patients. The resultant mean percent error of each estimated fetal weight from the actual birth weight, with its standard deviation, is shown in Table II. The p values for the results of a paired t test comparing the neural network model with the other models are also shown in Table II. The predictive value of the neural network is significantly better than the regression models of Hadlock and Shepard. The performance of the network over the weight range from >3800 to <4800 mg is shown in Fig. 4. Inclusion of parameters other than biparietal diameter, abdominal circumference, and femur length (gestational age, fundal height, amniotic fluid index, head circumference, subcutaneous tissue measurement, head circumference/abdominal circumference, femur length/abdominal circumference, sex, age, and gravidity, parity, and height) tends to have a smoothing effect on the estimated fetal weight because the errors are less systematic than with the Hadlock or Shepard formulas.

Data analysis with the neural network is not restricted to the reduction of large numbers of variables. When only the abdominal circumference and femur length are considered, as was done in the Hadlock model, the network performed as well as the Hadlock and Shepard formulas (Table I). If the weight range is restricted to >3800 and <4800 gm (because of the previous arguments) the resultant model has a statistically greater ($p < 0.005$) predictive value than either regression formula in the macrosomic weight range. The performance of this network model, however, is not as consistent over the entire weight range as the full network model (Fig. 3).

Another interesting observation from the study is the confirmation of the inaccuracy of Leopold examinations for the estimation of fetal weight. All infants, as part of the inclusion criteria, were estimated to be >4000 gm. Only 69.3% of the infants actually had birth weights >4000 gm.

We conclude that the neural network method of data analysis is a new technique that deserves further evaluation. Its ability to integrate numerous variables to develop a predictive model offers significant potential advantages over regression analysis. Its performance in the estimation of fetal weight in the clincially suspected macrosomic fetus is better than the traditional regression analysis used by Hadlock and Shepard if multiple parameters are considered. If the parameters are restricted to the abdominal circumference and femur length, as was done with the Hadlock formula, the network still predicts the estimated fetal weight significantly better than a regression formula does. The major drawback to this form of analysis is the necessity of including a sufficient number of patients over the entire range of birth weights, with the predictive value degrading significantly when this is not done.

Fetal echocardiography: Accuracy and limitations in a population at high and low risk for heart defects

Bryann Bromley, MD,[a] Judy A. Estroff, MD,[b, e] Stephen P. Sanders, MD,[g] Richard Parad, MD,[e, f] Drucilla Roberts, MD,[d] Fredric D. Frigoletto, Jr., MD,[a] and Beryl R. Benacerraf, MD[a, b]

Boston, Massachusetts

OBJECTIVE: Our objective was to assess the accuracy of prenatal echocardiography in detecting congenital heart defects in patients at high and low risk for structural cardiac anomalies.

STUDY DESIGN: Sixty-nine consecutive fetuses with congenital heart defects who had had prenatal ultrasonography at ≥18 weeks' gestation were evaluated to determine the accuracy of prenatal ultrasonography in identifying structural cardiac defects. Thirty-nine patients were at high risk and 30 patients were at low risk for cardiac anomalies. All fetuses were scanned with standard four-chamber and outflow tract views. Data concerning extracardiac anomalies and karyotypic abnormalities were tabulated. The accuracy of the four-chamber view alone in identifying congenital heart defects was evaluated.

RESULTS: Fifty-seven of 69 fetuses (83%) were prenatally identified ultrasonographically as having a heart defect. There was no difference in the sensitivity of detecting cardiac anomalies between high-risk and low-risk groups. When the four-chamber view was used, only 63% of fetuses were recognized as having an abnormal heart. Extracardiac anomalies were noted in 36% and karyotypic abnormalities in 17% of patients.

CONCLUSION: The four-chamber and outflow tract views done routinely in an ultrasonography laboratory seeing a mixed population of patients was successful in detecting 83% of fetuses with structural cardiac malformations. Because 43% of the fetuses with heart defects were referred for low-risk indications, systematic ultrasonographic examination of the fetal heart should not be reserved only for those at high risk. (Am J Obstet Gynecol 1992;166:1473-81.)

Key words: Fetal echocardiography, heart defects

Congenital heart defects occur in approximately eight of 1000 live births.[1] A family history of a congenital heart defect among first-degree relatives increases the risk to 4% to 12%.[2] In addition, patients with diabetes, phenylketonuria, and other noncardiac abnormalities are at increased risk for fetal cardiac anomalies. Although it is possible to catagorize certain fetuses as being at high risk for cardiac malformations, most neonates with a congenital heart defect were not perceived to be at increased risk prenatally.[3] The antenatal detection of cardiac malformations is crucial because obstetric and neonatal management is likely to be altered. The neonate with a significant cardiac lesion will benefit from delivery at a tertiary care center where the expertise of pediatric cardiologists and cardiac surgeons is readily available.

Fetal echocardiography is successful in identifying the majority of fetuses with structural cardiac abnormalities.[4-11] Most investigators have focused their attention on patients at high risk for cardiac lesions. The American Institute of Ultrasound in Medicine's guidelines advocate the use of the four-chamber view in the basic obstetric scan because this view is likely to identify disparity in chamber sizes, leading to a targeted cardiac evaluation.[12] Although some investigators suggest that the four-chamber view is adequate for detecting most cases of congenital heart disease, lesions involving the great vessels, such as tetralogy of Fallot and transposition of the great arteries, may be missed if the outflow tracts are not specifically examined.[7, 13]

Because prenatal diagnosis of congenital heart defects is critical to optimal neonatal care, we evaluated our accuracy in diagnosing congenital heart disease in a population that included patients at high and low risk for structural heart defects. In addition, we compared the sensitivity of our standard cardiac examination (four-chamber view and outflow tracts) with the sensitivity of the four-chamber view alone.

Material and methods

From Jan. 1, 1987, to Dec. 31, 1990, all neonates who were delivered at the Brigham and Women's Hospital or the Beth Israel Hospital and who had a diagnosis of congenital heart disease were identified with the special care nursery data base. During the same time period, all aborted fetuses delivered at the Brigham and Women's Hospital that were diagnosed as having a congenital heart defect were identified from the pathology data base. This information was then cross-referenced with records from our ultrasonography unit, yielding 69 neonates with congenital heart disease at birth and a prenatal sonogram in our ultrasonography laboratory at or after 18 weeks' gestation. The postnatal diagnosis of heart defects was made by autopsy, postnatal echocardiography, or cardiac catheterization. Neonates leaving the hospital without a recognized cardiac diagnosis were not included in the study.

Each patient in our ultrasonographic laboratory, regardless of the indication for the scan, is evaluated in a standard fashion. The cardiac portion of the examination includes the four-chamber view, short axis–long axis views, and views of the outflow tracts (Figs. 1A to 1E). Aortic and ductal arches were included when

possible. Each scan was done with an Acuson 128 variable focus imager (Acuson, Mountain View, Calif.) with a 3.5 MHz phased array transducer.

The prenatal ultrasonographic diagnosis of congenital cardiac disease was made prospectively and taken from the original report at the time of the scan. In addition, the four-chamber views of the prenatal scans were retrospectively reviewed without knowledge of the diagnosis to determine the sensitivity of the four-chamber view alone for detecting a cardiac malformation.

The patients were divided into high- or low-risk groups according to the indication for the scan, and the accuracy for detection of heart defects was analyzed separately for each group. The indications considered to represent an increased risk for congenital heart defects includes diabetes, referral from a level I facility for suspected cardiac abnormality, referral for a suspected noncardiac abnormality, a previous child with congenital heart disease, and phenylketonuria. Patients considered at low risk were scanned for placental position, growth, uncertain dates, abnormal α-fetoprotein level, possible polyhydramnios, maternal hypertension, previous stillbirth, postdate pregnancy, twins, and preamniocentesis evaluation.

Associated anomalies and karyotypic information were also tabulated. Pediatric follow-up was obtained

for all cases of antenatally diagnosed heart defects with delivery at the reference hospital to ascertain false-positive diagnoses.

Results

Sixty-nine fetuses were delivered at Brigham and Women's Hospital or Beth Israel Hospital and found by autopsy, postnatal echocardiography, or angiography to have an identified total of 131 cardiac lesions. Fifty-seven of the 69 patients (83%) were identified prenatally as having an abnormal heart and 83 of 131 lesions (66%) were correctly detected. Table I shows the cardiac defects and gestational ages at ultrasonographic diagnosis. Nearly all cases of ventricular hypoplasia, tetralogy of Fallot, and transposition of the great arteries were correctly identified. Most lesions that were missed were part of complex cardiac defects with multiple lesions, the other parts of which were correctly identified. Other defects commonly missed included abnormalities such as atrial septal defects, ven-

Fig. 4A. Normal-appearing four-chamber view of heart in 18-week fetus with tetralogy of Fallot. *LV*, Left ventricle; *RV*, right ventricle.

tricular septal defects, and valvar stenoses. Nine of 13 endocardial cushion defects were correctly detected; of the four missed, two were part of congenital heart abnormalities identified by the other lesions. Six of 10 fetuses with coarctation of the aorta were correctly identified, usually by the disparity in size between the left and right ventricles. All cases of pulmonic atresia and aortic stenosis were detected, although only half of the cases of pulmonic stenosis were correctly seen (Figs. 2 and 3). All cases of atrial septal defects, more than half the ventricular septal defects, and all cases of total anomalous pulmonary venous return were missed.

Follow-up of all fetuses with suspected congenital heart defects on a prenatal sonogram resulted in two false-positive diagnoses. Two patients had suspected ventricular septal defects at 20 and 22 weeks' gestation, respectively, with no evidence of heart disease at birth.

Twenty-five of the 69 fetuses (36%) had other congenital abnormalities detected by ultrasonography. These abnormalities included hydronephrosis or cystic kidneys ($n = 9$), thickened nuchal fold ($n = 4$), nonimmune hydrops ($n = 3$), abnormal distal extremities ($n = 3$), hydrocephalus ($n = 3$), duodenal atresia ($n = 2$), omphalocele ($n = 2$), agenesis of the corpus callosum ($n = 2$), hemivertebra ($n = 1$), absent stomach bubble ($n = 1$), adenomatoid cystic malformation of the lung ($n = 1$), holoprosencephaly ($n = 1$), cystic hygromas ($n = 1$), and pleural effusion ($n = 1$). In addition, 12 of 69 fetuses (17%) had an abnormal karyotype, including eight with trisomy 21, three with trisomy 18, and one with trisomy 13. Two of these fetuses had no ultrasonographic abnormalities other than the congenital heart defect.

Table II shows the various indications for ultrasonography and the correct or missed diagnoses by patient and by lesion in patients at high and low risk for congenital heart defects. Among the low-risk patients

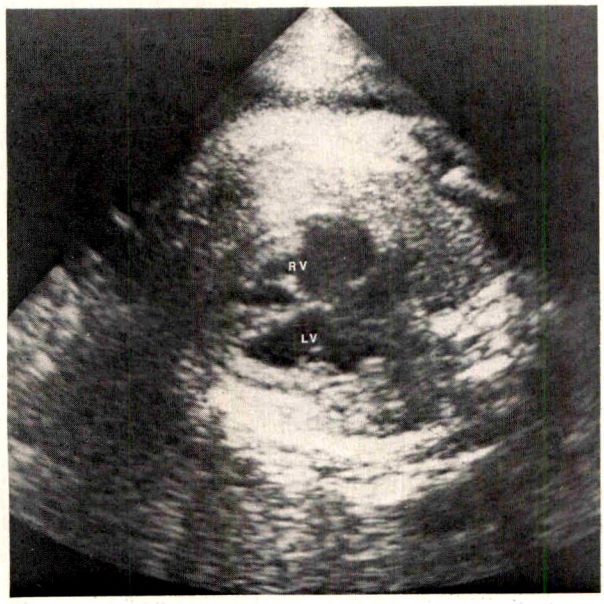

Fig. 5A. Normal-appearing four-chamber view of heart in 28-week fetus with transposition of great arteries. *LV*, Left ventricle; *RV*, right ventricle.

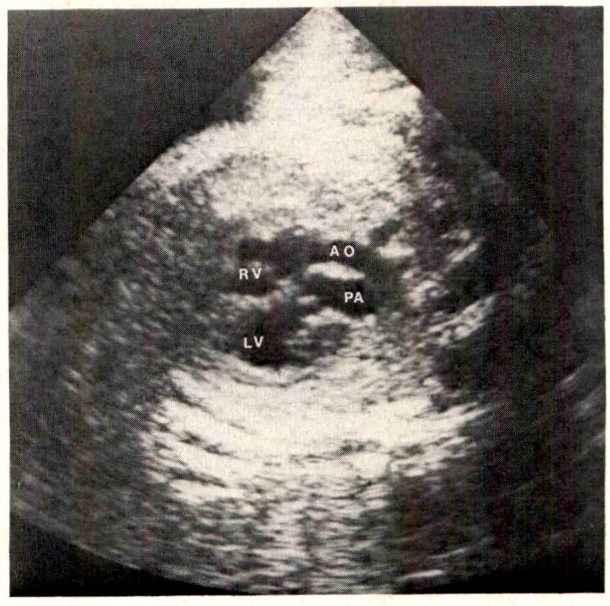

Fig. 5B. Short-axis view of same fetus showing parallel course of two great vessels. *LV*, Left ventricle; *RV*, right ventricle; *AO*, aorta; *PA*, pulmonary artery.

Table III. Comparison between standard scan and four-chamber view only

	Identified		
	No.	*%*	*Missed*
Standard scan			
Lesions	86	66	45
Patients	57	83	12
*Four-chamber view only** (n = 67)			
Patients	42	63	25

Fifteen lesions in 13 fetuses; two fetuses had two lesions missed.

*Missed on four-chamber view but identified with standard scan. Transposition of great vessels, n = 4; tetralogy of Fallot, n = 7; coarctation of aorta, n = 1; ventricular septal defect, n = 2; Interrupted inferior vena cava, n = 1.

(n = 30), 25 fetuses were correctly identified as having congenital heart defects, resulting in a sensitivity of 83%. There were 41 specific lesions correctly identified and 21 missed, for a lesion-specific sensitivity of 66%. There were 39 fetuses at risk for cardiac anomalies, 32 of whom had congenital heart defects diagnosed prenatally, resulting in a sensitivity of 82%. Forty-five of 69 lesions were correctly identified in the high-risk group, for a lesion-specific sensitivity of 65%.

On retrospective evaluation, the four-chamber view was of adequate quality in 67 of the 69 patients. The cardiac abnormality was detected in only 42 of these 67 patients (63%). Table III shows lesions with a normal-appearing four-chamber view detected prenatally with the short-axis view or views of the outflow tracts. Fifteen lesions in 13 fetuses would have been missed had the four-chamber view been used exclusively, including seven cases of tetralogy of Fallot and four cases of transposition of the great arteries (Figs. 4A, 4B, 5A, 5B, 6A, and 6B). Specifically, in the high-risk group we would have missed two fetuses with tetralogy of Fallot, two with transposition of the great arteries, and one with a ventricular septal defect. In the low-risk group analysis of the four-chamber view alone would have resulted in a missed diagnosis of tetralogy of Fallot in five fetuses, transposition of the great arteries in two fetuses, coarctation of the aorta and a ventricular septal defect in one fetus, and an interrupted vena cava in one of the fetuses with tetralogy of Fallot. Ten of the 13 fetuses with a normal-appearing four-chamber

view in spite of a heart defect had no extracardiac anomalies.

Comment

Prenatal identification of fetuses with congenital heart defects is of paramount importance, because these infants are likely to benefit from delivery at a tertiary care center where the neonate can be stabilized, the diagnosis confirmed, and corrective or palliative procedures undertaken.

Fetal echocardiography has been shown to be an accurate method for diagnosing structural cardiac malformations in fetuses at high risk.[4-11] Standard echocardiographic views permitted us to detect congenital heart disease in 57 of 69 patients (83%). Many of the lesions that were not recognized in our series were ei-

ther parts of a complex congenital heart pattern or isolated abnormalities such as septal defects, valvar stenoses, and coarctation of the aorta. These findings are in agreement with those of Crawford et al.,[8] who accurately predicted 74 cases of congenital heart disease and reported an additional 17 false-negative cases. Missed diagnoses in their series also consisted primarily of ventricular septal defects, coarctation of the aorta, and valvar stenoses. Marasini et al.[9] reported seven cases of congenital heart disease correctly identified in utero, with three false-negative diagnoses, again involving primarily ventricular septal defects and coarctation of the aorta. Parness et al.[10] correctly identified 10 of 14 cases of congenital heart disease in the midtrimester of pregnancy. Copel et al.[7] reported a high sensitivity (92%) for detecting congenital heart disease in a referral population.

Noncardiac malformations have been identified in as many as 25% to 50% of patients with congenital heart disease.[14, 15] Our data concur with previous reports; 25 of 69 fetus (36%) with heart defects had other ultrasonographically detectable anomalies. In addition, 17% of our study population had an abnormal karyotype. This is similar to the 19% incidence of aneuploidy reported by Ferrazzi et al.[11] Berg et al.[16] report the incidence of aneuploidy as 13% at birth in those patients with congenital heart disease, whereas Copel et al.[17] reported that 32% of the fetuses in their study had an abnormal karyotype. Thus we confirm the recommendation for karyotypic evaluation of the fetus with structural cardiac disease.

Although echocardiography has been advocated for fetuses at high risk for congenital heart disease, the majority of fetuses actually diagnosed with cardiac malformations have no identifiable risk factors.[3] In this study 30 of 69 fetuses (43%) identified as having a heart defect were initially referred for ultrasonography because of low-risk indications. It is our practice to examine the fetal heart in a standard fashion, regardless of the indication for scanning. In all fetuses of ≥18 weeks' gestation, we evaluate the four-chamber view and the right and left ventricular outflow tracts. Our data demonstrate that this comprehensive evaluation resulted in the identification of 83% of cardiac abnormalities in patients at low risk for congenital heart disease and that we were as successful in diagnosing congenital heart disease in the low-risk as in the high-risk populations.

Copel et al.[7] have reported a sensitivity of 92% in detecting congenital heart disease by means of the four-chamber view. In our experience evaluation of the four-chamber view alone would have allowed identification of only 42 of 67 patients with congenital heart disease, a sensitivity of only 63%. Specifically, seven cases of tetralogy of Fallot and four cases of transposition of the great arteries would have been missed. These cardiac defects can be life-threatening at birth if undetected. DeVore et al.[18] report that 7% to 10% of infants with congenital heart disease have tetralogy of Fallot and that this diagnosis is often missed on the four-chamber view. We speculate that the higher sensitivity of the four-chamber view for identifying heart defects in the study by Copel et al. is due to their patient referral pattern. Twenty of 74 patients identified were initially referred because of a suspicious level I scan (presumably an abnormal four-chamber view).

An unavoidable limitation of this study was the selection of a patient population delivered at two major teaching hospitals. It is, however, agreed that most fetuses with congenital heart defects would have been delivered at Brigham and Women's or Beth Israel Hospital because of the availability of pediatric services. Furthermore, this ultrasonography laboratory serves these two teaching hospitals primarily, and therefore the design of this study was deemed adequate.

Our sensitivity for identifying congenital heart defects has improved since our previous study published 3 years ago on a similar patient population.[3] This may be due, in part, to our ability to identify outflow tracts more consistently. It is also evident that cardiac lesions, such as atrial septal defects, ventricular septal defects, and valvar stenoses, still elude prenatal diagnosis. Further follow-up of the eight children with ventricular septal defects missed ultrasonographically (and not part of more complex cardiac defects) revealed that five did not require surgical intervention and are undergoing medical follow-up. The other three children are doing well after surgical repair. Venous abnormalities are also difficult to diagnose antenatally. We found only limited published data concerning prenatal detection of venous abnormalities, and most are associated with complex congenital heart disease.[19]

In conclusion, we believe that all obstetric scans performed at or after 18 weeks' gestation should include evaluation of the ventricular outflow tracts and a four-chamber view of the heart, regardless of whether the patient is known to be at increased risk for having a child with a congenital heart anomaly. The four-chamber view alone would not have allowed detection of 11 cases of either tetralogy of Fallot or transposition of the great arteries. Forty-three percent of fetuses with structural cardiac anomalies in this study were not considered at high risk and might have been overlooked had the fetal heart not been examined systematically. In addition, 64% of fetuses had no extracardiac abnormalities that would have led to a referral for a targeted scan. Should an abnormality in the fetal heart be detected ultrasonographically, referral to a more experienced echocardiographer is reasonable to ascertain a specific diagnosis. The patient may then be appropri-

ately counseled, and karyotypic evaluation and delivery at an appropriate institution can be undertaken.

In situ and invasive vulvar cancer incidence trends (1973 to 1987)

Susan R. Sturgeon, DrPH,[a] Louise A. Brinton, PhD,[a] Susan S. Devesa, PhD,[b] and Robert J. Kurman, MD[c]

Bethesda and Baltimore, Maryland

OBJECTIVE: The objective of this study was to examine recent trends in the incidence of vulvar cancer.
STUDY DESIGN: Cases of in situ and invasive squamous cell vulvar cancer were identified from nine Surveillance, Epidemiology, and End Results cancer registries.
RESULTS: The incidence rate of in situ vulvar cancer nearly doubled between 1973 to 1976 and 1985 to 1987, whereas the rate of invasive squamous cell carcinoma remained relatively stable.
CONCLUSIONS: Possible reasons for this discordance include the following: (1) Women affected by the "sexual revolution" are not yet old enough to have invasive vulvar carcinoma; (2) early diagnosis and treatment of in situ carcinoma have mitigated anticipated increases in invasive vulvar carcinoma incidence; (3) in situ and invasive carcinomas of the vulva have different etiologies, with the sexually transmitted human papillomavirus involved in the etiology of in situ carcinoma and other factors involved with most invasive squamous cell carcinoma. (AM J OBSTET GYNECOL 1992;166:1482-5.)

Key words: Vulvar cancer, incidence rates, time trends

Cancer of the vulva is rare, with an average annual age-adjusted incidence rate for invasive disease in the United States of 1.6 per 100,000 women.[1] Epidemiologic studies have shown that risk factors for vulvar cancer include multiple sexual partners, a prior infection with genital warts, current cigarette smoking, and a prior abnormal cervical Papanicolaou smear.[2, 3] Since sexual behavior and smoking practices of women in the United States have changed dramatically over the last two decades,[4, 5] an examination of recent trends in the incidence of vulvar cancer is of interest.

Material and methods

Cases of in situ and invasive squamous cell carcinoma of the vulva diagnosed between 1973 and 1987 were identified through nine population-based cancer registries participating in the Surveillance, Epidemiology, and End Results (SEER) program: Atlanta, Detroit, San Francisco–Oakland, Seattle–Puget Sound, Connecticut, Iowa, New Mexico, Utah, and Hawaii.[1, 6] Although not based on a probability sample, these geographic areas cover about 10% of the United States population. Mortality rates for the SEER program and the total United States are similar for many types of cancer and were identical for vulvar cancer in 1973 to 1977 (0.4/100,000 woman years).[1]

In this analysis we examined cancer incidence for squamous cell tumors arising in the vulva, labia, and clitoris (International Classification of Diseases for Oncology topography codes 184.1 to 184.4), including carcinomas not otherwise specified (International Classification of Diseases for Oncology morphology codes 8010, 8030, 8050 to 8081, 8123).[7] The analysis was restricted to the 2948 in situ and 2346 invasive squamous cell tumors on the basis of the assumption that the etiology of vulvar cancer, like cancer of the cervix, differs according to histologic type.[8] Non-squamous-cell malignancies were excluded, accounting for 1% and 21.8% of all reported in situ and invasive cancers, respectively. The cell-type distribution of excluded invasive cancers was as follows: basal cell carcinoma (n = 205), Paget's disease (n = 123), other and unspecified adenocarcinomas (n = 61), malignant melanoma (n = 203), sarcomas (n = 34), and other or not specified types (n = 28). Population estimates for the calculation of incidence rates were provided by SEER program staff[9] and were generally based on data from the United States Census Bureau.

Results

The annual incidence of in situ vulvar carcinoma for all races combined nearly doubled from 1.1 to 2.1 per 100,000 woman years, during the period from 1973 to 1976 and 1985 to 1987, surpassing the rate for invasive squamous cell carcinoma (Fig. 1). The largest proportional increase occurred among white women <35

years old, for whom the rate nearly tripled (Table I). Increases were more modest among black women than among white women, with the rate not quite doubling among black women <35 years old. In situ rates among blacks of all ages were higher than those among whites before 1977, but the black-white differential has diminished in more recent years. The peak in situ rate has shifted over time from women >54 years old to women aged 35 to 54.

The invasive squamous cell carcinoma incidence for all races combined was relatively stable over 1973 to 1976 and 1985 to 1987 (Fig. 1). Rates in each age group were also relatively steady, although among white women they tended to decline among those aged ≥55 (Table II). Little racial difference was evident under age 35; rates were higher at ages 35 to 54 among blacks and at ages >54 among whites. In contrast to in situ rates, invasive rates increased steadily with age. It should be noted that some of the age-specific in situ and invasive rates among blacks were based on small numbers of cases.

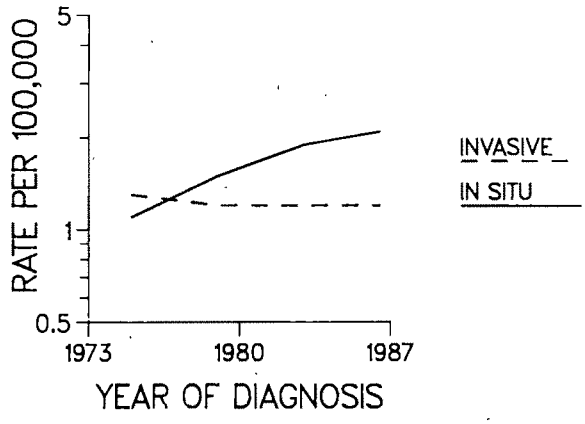

Fig. 1. Age-adjusted trends in squamous cell cancer of the vulva among all races combined (1970 vs standard).

Comment

The incidence of in situ vulvar carcinoma nearly doubled between the period from 1973 to 1976 and 1985 to 1987, with the rate among whites and younger women rising faster than the rate among blacks and older women. The increase for in situ carcinoma was not paralleled by an increase in invasive squamous cell carcinoma; its incidence was relatively steady over the same period.

We first considered whether the observed rise in the incidence of in situ carcinoma might be a data artifact resulting from changes in the classification system for vulvar intraepithelial cancer. Before 1984 lesions were divided into two broad categories: dysplasia (mild, moderate, and severe) and carcinoma in situ. Because of problems in reproducibly distinguishing severe dysplasia from carcinoma in situ, it was proposed that these two lesions be combined into one category, grade 3 vulvar intraepithelial neoplasia.[10] This revision was widely but not universally adopted by pathologists in the United States. Over the time period examined in this study, however, eight of nine SEER registries did not include cases of grade 3 vulvar intraepithelial neoplasia unless there was also specific mention of carcinoma in situ on the pathology report. Although one registry did include cases of grade 3 vulvar intraepithelial neoplasia diagnosed between 1984 and 1987, this registry contributed <5% of the total number of in situ cases reported during this time period. Our finding that the increase in the incidence of in situ carcinoma began before 1983 and continued steadily through 1985 to 1987 also argues against the revised classification scheme being responsible for the observed increase of in situ carcinoma. It is instead more likely that some in situ carcinomas have been missed and that rates of in situ carcinoma after 1983 are an underestimate of the true incidence of this condition.

The diagnosis of preinvasive disease is complicated by its similarity in clinical appearance and symptoms to some benign diseases that are commonly seen in the vulva.[11] It has also been suggested that an increasing propensity to perform a biopsy on questionable lesions might account for the observed increase of in situ vulvar cancer.[12] We have no data to examine temporal trends in the frequency of vulvar lesion biopsies. However, as the proportion of women who had ever had a Papanicolaou smear increased from 83% to 95% between 1973 and 1987,[13] opportunities for examination of the vulva in the absence of symptoms have undoubtedly increased over time. On the other hand, the greatest gains in Papanicolaou smear use have occurred among blacks and the elderly,[13] a pattern that does not readily account for the larger increases of in situ vulvar carcinoma among whites and younger women.

Although only a few epidemiologic studies of vulvar cancer have been conducted, a sexually related etiology is suspected in view of the increased risk associated with an increased number of lifetime sexual partners and a history of genital warts.[2, 3] Over the past two decades changes have occurred in the sexual practices in the United States that might explain the increased incidence of in situ vulvar carcinoma. A study conducted in 1983 revealed that the mean number of lifetime sexual partners was 1.3 and 1.9 times higher among women <35 years old than among women ≥55 years old, among blacks and whites, respectively.[4] This is consistent with the larger proportional increase of in situ vulvar carcinoma among younger women than older women and with the larger relative increase among whites compared with blacks.

In contrast, in spite of changes in sexual activity over

the last two decades, the incidence of invasive squamous cell carcinoma of the vulva has not increased. The apparent inconsistency between the incidence of in situ and invasive carcinoma may be because the cohort of women affected by the sexual revolution has not yet reached the age when invasive vulvar carcinoma would develop. Another possible explanation could be that early diagnosis and treatment of in situ lesions have mitigated anticipated increases in invasive carcinoma incidence. Recent data, however, support another explanation. Studies of the effects of sexual behavior on risk have focused on the human papillomaviruses as a possible etiologic agent because vulvar carcinoma is often associated with preexisting or coexisting condyloma acuminatum.[14, 15] More recently, specific human papillomavirus genotypes have been detected within invasive and in situ vulvar carcinomas.[16] Preliminary virologic evidence reveals that the majority of invasive vulvar carcinomas are not associated with human papillomavirus,[16] whereas most in situ vulvar carcinomas are human papillomavirus related,[17-19] suggesting that these two conditions may be distinct etiologic entities. Studies showing that in situ vulvar cancer rarely progresses to invasive vulvar carcinoma[15, 20] also support the view that the majority of invasive vulvar squamous cell carcinomas may be unrelated to in situ vulvar cancer, possibly explaining why changes in sexual behavior are consistent with in situ but not invasive vulvar cancer trends. Some additional support for different etiologies of these lesions is derived from the epidemiologic finding that multiple sexual partners is a stronger risk factor for in situ than for invasive vulvar cancer,[2] although this has not always been observed.[3]

Some interest has focused on the role of risk factors other than human papillomavirus in the etiology of vulvar cancer. Cigarette smoking has been shown to be a risk factor for both in situ and invasive vulvar cancer,[2, 3] with the excess risk largely restricted to current smokers. Since the prevalence of current cigarette smoking declined slightly between 1973 and 1987 among women between 20 and 64 years old and remained steady among women ≥65 years old,[4] temporal

changes in cigarette smoking are not consistent with the observed increase in the incidence of in situ vulvar cancer. Smoking also explains little of the incidence trends in invasive vulvar cancer, which were stable except for among women ≥55 years old.

Two possible but as yet unconfirmed risk factors for in situ vulvar cancer are the use of oral contraceptives and exogenous estrogens in combination with progesterone.[2,3] The cohort of women maximally exposed to oral contraceptives were in their 20s in the 1960s, 30s in the 1970s, and 40s in the 1980s.[21] Women between 35 and 54 years old in the 1980s were more likely to have been previously exposed to oral contraceptives than women in this same age group in the 1970s, consistent with the increasing trend in the incidence of in situ vulvar cancer among women between 35 and 54 years old. However, few women >55 years old during the period of this study were ever exposed to oral contraceptives. Thus oral contraceptive use most likely cannot explain the increasing trend in the incidence of in situ vulvar cancer among older women. The increasing incidence among young women also contrasts with the declining prevalence of oral contraceptive use among women <35 years old from the 1970s to the 1980s.

The prescribing of a progestin along with estrogen for menopausal women was uncommon before the mid-1980s.[22] Because its use has risen substantially since then, the future experience of older women with respect to in situ vulvar cancer should be monitored.

In summary, we have confirmed using population-based data several clinical reports that the incidence of in situ carcinoma of the vulva is increasing.[23-25] Some of the increase may be due to heightened awareness of this entity over time. However, it is more likely that changes in sexual behavior have been responsible for the observed increases. This interpretation is supported by studies that have found human papillomavirus deoxyribonucleic acid in a high proportion of vulvar carcinoma in situ lesions. Contrary to expectation, there has been no parallel increase in the incidence of invasive squamous cell carcinoma. A possible explanation for this discordance is that in situ and invasive vulvar cancer have different etiologies, as suggested by recent pathologic and virologic studies that have implicated human papillomavirus in the development of most vulvar carcinomas in situ[17] but not in most invasive carcinomas.[18-20]

Comprehensive fetal assessment with three ultrasonographic characteristics

David K. James, MD, Michael J. Parker, MD, and John S. Smoleniec, MB
Bristol, England

OBJECTIVES: When three ultrasonographic characteristics—umbilical artery Doppler recording, growth (abdominal circumference), and biophysical profile score—are used in combination in assessment of fetuses at risk of chronic asphyxia; (1) What are the order and time scale for the development of abnormality with each characteristic? (2) What is the short-term outcome associated with abnormalities of the three characteristics? (3) Should we amend our fetal assessment protocol?
STUDY DESIGN: An audit of 103 fetuses (100 mothers) referred to a tertiary center for fetal assessment because of suspected chronic fetal asphyxia was performed with three ultrasonographic characteristics, umbilical artery Doppler recording, measurement of abdominal circumference, and documenting the biophysical profile score.
RESULTS: The order of deterioration (which had a very variable time scale) was umbilical artery Doppler recording, followed by abdominal circumference and finally biophysical profile score. Normal characteristics or an abnormal umbilical artery Doppler recording alone or an abnormal abdominal circumference alone was associated with an excellent prognosis. The worst outcome was found in the 28 fetuses with abnormality of all three ultrasonographic features before delivery.
CONCLUSIONS: The main suggested implications for management are avoidance of preterm delivery with normal ultrasonographic characteristics, an abnormal umbilical artery Doppler recording alone, or an abnormal abdominal circumference alone; delivery of fetuses at ≥34 weeks with abnormal umbilical artery Doppler recording and abdominal circumference before the biophysical profile score becomes abnormal; and implementation of specific measures to prevent necrotizing enterocolitis in newborns when all three characteristics are abnormal. (Am J Obstet Gynecol 1992;166:1486-95.)

Key words: Fetal assessment, umbilical artery Doppler, fetal growth, biophysical profile score

Ultrasonography is used to assess the fetus at risk for chronic asphyxia.[1] The three characteristics studied and used in clinical practice are umbilical artery Doppler recordings,[2] measurements of fetal size,[3] and biophysical measurements such as the nonstress test (NST)[4] or the biophysical profile score.[5] Abnormalities of umbilical artery Doppler recording and fetal growth are both associated with poor fetal outcome[6, 7]; however, they are probably affected relatively early in the pathologic process.[8] In contrast, abnormalities of biophysical measurements (NST or biophysical profile score) probably occur relatively late and reflect the degree of imminent fetal risk.[8] The clinical dilemma faced in such cases is when to deliver. Elective delivery when the umbilical artery Doppler recording or growth is abnormal may be unnecessarily premature; many of the problems of such babies after birth are related to preterm delivery rather than the asphyxial process directly.[9, 10] Conversely, leaving the fetus in utero until the biophysical profile score is abnormal may put the fetus at an increased risk.

Over the past 3 years we have followed an agreed protocol of fetal assessment in such cases, using all three ultrasonographic characteristics. The aims of this audit of our 3-year experience with this approach were: (1) to determine the order in which the three ultrasonographic characteristics become abnormal, (2) to document the short-term outcome, (3) to establish the variation in time scale of deterioration of the three characteristics, and (4) to amend, if necessary, our fetal assessment protocol.

Patients and methods

Since October 1987 patients referred to the Fetal Assessment Unit in Bristol with suspected chronic fetal asphyxia have had fetal assessment in accordance with an accepted protocol. At the first assessment structural abnormality is excluded by ultrasonography, circumferences of the fetal head and abdomen, are measured, umbilical artery Doppler recording is recorded, and biophysical profile score is obtained.[11]

Scoring for each of the five components of the biophysical profile score is in accordance with the original system used by Manning et al.,[12] namely, score of 2 each

in a 30-minute observation for (1) one episode of fetal breathing of 30 seconds, (2) three or more discrete body or limb movements, (3) one episode of limb flexion-extension-flexion (tone), and (4) visualization of one or more amniotic fluid pockets measuring 10 mm in two perpendicular planes.

If the fetus is very small or has a structural abnormality, fetal karyotyping is also performed. If the fetus is structurally normal, the frequency of subsequent assessments depends on the umbilical artery Doppler recording and the head and abdominal circumference values. If these values are normal, umbilical artery Doppler recording and biophysical profile score are recorded weekly and growth is measured every 2 weeks. However, if the umbilical artery Doppler recording is abnormal (defined as a pulsatility index >2 SD above the mean for gestation,[13] absent end-diastolic recording, or reverse flow in diastole) or the size or growth is abnormal (defined as an abdominal circumference measurement <2 SD below the mean for gestation,[14] umbilical artery Doppler recording and biophysical profile score are recorded at least twice weekly and growth is measured every 2 weeks. The decision to deliver is taken by the consultant unit in charge of the case on the basis of both maternal and fetal condition. However, it is the policy of the Fetal Assessment Unit to advise delivery if the biophysical profile score is <8 to 10 on extended testing over 1 hour. In this 3-year audit (Oct. 1, 1987, to Sept. 30, 1990) the indications for referral and delivery were noted in each case. Perinatal outcome in terms of mortality and morbidity up to 4 weeks of age were recorded.

Statistical analysis was undertaken with nonparametric methods, χ^2 with Yates' correction for comparison of frequencies and Mann-Whitney U for comparison of medians. The level of statistical significance used in the study was $p < 0.05$.

Results

During the 3-year period 100 women had suspected chronic fetal asphyxia and were referred for fetal assessment. The indications were hypertension alone (40 patients), clinically diagnosed small for gestational age (SGA) alone (25 patients), hypertension and SGA (32 patients), and twins (three patients).

Ultrasonographic characteristics

At referral and subsequent progress. At referral the 103 fetuses could be subdivided into five subgroups according to the initial ultrasonographic characteristics.

GROUP A′: HYPERTENSION ALONE WITH NORMAL ULTRASONOGRAPHY (UMBILICAL ARTERY DOPPLER RECORDING, ABDOMINAL CIRCUMFERENCE, AND BIOPHYSICAL PROFILE SCORE). There were initially 25 fetuses in this group. The median amniotic fluid volume was 32 mm (range 23 to 59 mm). Twenty-three continued with normal ultrasonographic features until delivery. The median referral-to-delivery interval for these 23 fetuses was 1 day (range 1 to 32). Two fetuses (8%) had elevated pulsatility index values 9 and 12 days after referral, respectively.

GROUP B′: LOW ABDOMINAL CIRCUMFERENCE MEASUREMENT ONLY. All 16 fetuses in this group persisted with a low abdominal circumference as the only ultrasonographic abnormality until delivery. The median amniotic fluid volume was 29 mm (range 17 to 36 mm) and was <20 mm in only one case (17 mm). In all cases where repeated measurements were made, the abdominal circumference growth paralleled the expected normal growth trajectory but at <2 SD below the mean. The median referral-to-delivery interval for these 16 fetuses was 10 days (range 1 to 51).

GROUP C′: ABNORMAL UMBILICAL ARTERY DOPPLER RECORDING ONLY. The median amniotic fluid volume of the 20 fetuses initially in this group was 31 mm (range 29 to 40 mm). Twelve (60%) had elevated pulsatility index values as the initial Doppler abnormality, and eight (40%) had absent end-diastolic recording. In addition, two fetuses from the initial subgroup A′ hypertension alone had elevated pulsatility index values (see above); thus there were 22 fetuses with abnormal umbilical artery Doppler recording alone either at referral or subsequently. Seven of these 22 fetuses (31.8%) (all with elevated pulsatility index values and including the two from the hypertension subgroup A′) manifested no other ultrasonographic abnormality until delivery, which was 7 days later (median) (range 1 to 34 days). The remaining 15 fetuses (68.2%) subsequently manifested poor growth with the abdominal circumference measurements falling to <2 SD below the mean 21 days later (median) (range 14 to 56 days). Of these 15 fetuses with abnormal umbilical artery Doppler recording and low abdominal circumference, 13 (86.7%) manifested no other ultrasonographic abnormality until delivery. The median interval between development of a low abdominal circumference and delivery was 1 day (range 1 to 23 days). The other two fetuses (13.3%) subsequently had an abnormal biophysical profile score 3 and 7 days, respectively, from the time a low abdominal circumference was manifested. They were both delivered within 1 hour of the abnormal biophysical profile score.

GROUP D′: ABNORMAL UMBILICAL ARTERY DOPPLER RECORDING AND LOW ABDOMINAL CIRCUMFERENCE. There were initially 33 fetuses in group D′. The median amniotic fluid volume of the group was 33 mm (range 20 to 78 mm). Fourteen of these (42.4%) had elevated pulsatility index as the Doppler abnormality and 19 (57.6%) had absent end-diastolic recording. Sixteen fetuses (48.5%) (10 with elevated pulsatility index and six with absent end-diastolic recording) did not have any

other ultrasonographic abnormality until delivery, which was 2 days later (median) (range 1 to 33 days). However, 17 (51.5%) (four with elevated pulsatility index and 13 with absent end-diastolic recording) subsequently manifested an abnormal biophysical profile score after a further 7 days (median) (range 1 to 26 days) and were delivered within 1 hour of the biophysical profile score.

GROUP E′: ABNORMAL UMBILICAL ARTERY DOPPLER RECORDING, LOW ABDOMINAL CIRCUMFERENCE, AND BIOPHYSICAL PROFILE SCORE <8/10. The median amniotic fluid volume in the group was 30 mm (range 12 to 90 mm), with the value being <20 mm in five of the nine cases. Seven fetuses had absent end-diastolic recording and two had reverse flow as the Doppler abnormalities. Seven of these fetuses (77.8%) were delivered within 1 hour. The eighth fetus was discovered to have trisomy 18 after a fetal karyotype determination was performed on placental biopsy material. Labor was induced, and vaginal delivery of a stillborn infant followed. In the final case, referred at 31 weeks, the fetus was considered to be too small for survival by the unit in charge of the case, and the decision was made not to perform an emergency cesarean section. Fetal death occurred within 48 hours, labor was induced, and a 750 gm fetus was delivered vaginally.

Immediately before delivery. The 103 fetuses were divided into five subgroups according to the final ultrasonographic characteristics immediately before delivery.

GROUP A: NORMAL ULTRASONOGRAPHY (UMBILICAL ARTERY DOPPLER RECORDING, ABDOMINAL CIRCUMFERENCE, AND BIOPHYSICAL PROFILE SCORE) (HYPERTENSION ALONE) (23 FETUSES). The median number of assessments performed in this group was one (range one to seven). The median amniotic fluid volume of the group before delivery was 32 mm (range 23 to 59 mm).

GROUP B: LOW ABDOMINAL CIRCUMFERENCE MEASUREMENT ONLY (16 FETUSES). The median number of assessments performed in this group was two (range one to six). The median amniotic fluid volume of the group before delivery was 29 mm (range 19 to 40 mm) with the volume being <20 mm in only one case (19 mm).

GROUP C: ABNORMAL UMBILICAL ARTERY DOPPLER RECORDING (SEVEN FETUSES). The median number of assessments performed in this group was one (range one to ten). The median amniotic fluid volume of the group before delivery was 31 mm (range 30 to 40 mm).

GROUP D: ABNORMAL UMBILICAL ARTERY DOPPLER RECORDING AND LOW ABDOMINAL CIRCUMFERENCE (29 FETUSES). The median number of assessments performed in this group was three (range one to 11). The

median amniotic fluid volume of the group before delivery was 30 mm (range 11 to 75 mm) with the volume being <20 mm in five cases.

GROUP E: ABNORMAL UMBILICAL ARTERY DOPPLER RECORDING, LOW ABDOMINAL CIRCUMFERENCE, AND BIOPHYSICAL PROFILE SCORE <8/10 (28 FETUSES). The median number of assessments performed in this group was two (range one to 15). The median amniotic fluid volume of the group before delivery was 20 mm (range 5 to 90 mm) with the volume being <20 mm in 10 cases and <10 mm in only one case (5 mm).

Of the 28 fetuses with failure to achieve a normal biophysical profile score of 8/10 or 10/10, 25 (89.3%) failed to score on the NST–cardiotocograph, 23 (82.1%) on fetal breathing, 19 (67.9%) on fetal tone, 13 (46.4%) on fetal movement, and only one fetus (3.6%) had an amniotic fluid volume <10 mm.

Dexamethasone was given in six cases before delivery, three each from the final subgroups D and E.

Obstetric details. The general characteristics of the final five subgroups are summarized in Table I. When the indication for referral was hypertension alone, the likelihood of a fetus manifesting an abnormal biophysical profile score at referral or subsequently was only 2.5% (one of 40). The risks of an abnormal biophysical profile score in women referred for SGA alone or SGA and hypertension were 24% (six of 25) and 65.6% (21 of 32), respectively.

The obstetric characteristics of the final five subgroups at referral and delivery are summarized in Table II. The median gestation at referral for groups D and E (32 weeks) was significantly lower than that of groups A, B, and C (36 weeks) ($p < 0.0001$). There was no significant difference between groups D and E in gestation at referral; however, at delivery the median gestation of group D (36 weeks) was significantly greater than that of group E (32.5 weeks) ($p < 0.001$).

The delivery details of the final five subgroups are summarized in Table III. There was a high cesarean section rate for all five subgroups (the overall rate for the hospital was 10.2% in 1990). Seven of the 28 fetuses with an abnormal biophysical profile score (group E) (25%) had labor induced. In addition, four of the seven (57.1%) were delivered vaginally. Only 14 babies from group E had cord pH estimation at birth, but eight (57.1%) had a pH of ≥7.25.

Fetal karyotype. Ten fetuses (9.7%) (one in group D and nine in group E) had chromosome analysis (nine by placental biopsy and one by fetal blood sampling) after referral. One of the 10 was abnormal (trisomy 18). One baby from group E was discovered to have trisomy 18 after birth. Two more patients had karyotyping because of maternal age in the first half of pregnancy. The two cases of chromosomal abnormality were associated with large amniotic fluid volumes (75 and 90 mm, respectively).

Fetal outcome. The outcome of the five groups is summarized in Tables IV and V. All seven deaths occurred in group E. Two were fetal deaths in utero, one with trisomy 18 (31 weeks, 860 gm) and one normal fetus where the clinical decision was taken not to deliver the fetus (31 weeks, 750 gm). There were two first-week deaths. The first (29 weeks, 650 gm) was a sudden death caused by a large intraventricular hemorrhage

Indication for delivery: fetal, the fetal condition (biophysical profile score <8/10); maternal, the maternal condition (uncontrollable hypertension, symptoms, renal compromise, liver enzyme abnormality, or clotting disturbance); maturity, the pregnancy had reached a gestation where the risks from preterm delivery were considered small; spontaneous, spontaneous onset of labor.

*Values in parentheses represent percent of those in labor.

†Number of those tested with low values per total number tested.

with no respiratory distress on the second day of life. The second case (32 weeks, 1230 gm) was a baby with trisomy 18 who died on the second day; karyotyping was not possible because the fetus was seen on a weekend with abnormality of all three ultrasonographic characteristics. An emergency cesarean section was performed. Two babies died of necrotizing enterocolitis at 10 days (35 weeks, 1780 gm) and 16 days (29 weeks, 670 gm), respectively. The final death occurred at 10 days (27 weeks, 660 gm) from severe respiratory distress syndrome and extensive intraventricular hemorrhage.

Most of the neonatal morbidity was found in groups D and E. Furthermore, in view of the higher incidence of preterm delivery in group E, it is not surprising that babies from group E had more neonatal problems, compared with those from group D.

The differences in outcome between groups D and E could be due to the effects of preterm delivery rather than the abnormal biophysical profile score. Furthermore, nine of the fetuses in group E had an abnormal biophysical profile score and thus did not necessarily reflect any consequences of a clinical decision to wait for the biophysical profile score to become abnormal. Thus we compared the outcome of 14 normal fetuses from group E, with initially abnormal umbilical artery Doppler recording and low abdominal circumference alone who subsequently had an abnormal biophysical profile score, with those of a matched cohort of 14 fetuses from group D, who were delivered at the same gestational age but who never manifested an abnormal biophysical profile score. The outcomes are compared in Table VI. In spite of the matched gestations there were still more complications in group E. Severe complications exclusively found in this group were those that caused the two deaths, respiratory distress syndrome complicated by air leaks and bronchopulmonary dysplasia, intraventricular hemorrhage, neurologic abnormalities, and necrotizing enterocolitis. Although babies in group E had a higher incidence of respiratory distress syndrome alone and jaundice and a lower incidence of no problems, none of these differences were statistically significant.

Comment

Fetal blood gas values and acid-base status are abnormal in chronic fetal asphyxia, but recent work has suggested that measurement of these criteria obtained

by potentially hazardous invasive procedures does not provide an accurate guide to prognosis.[9] That work demonstrated that the gestional age at delivery was the most important prognostic factor. Unanswered questions therefore remain. With chronic fetal asphyxia is it better to "buy time" by avoiding preterm delivery and allowing the opportunity for steroid therapy,[10] or is this approach associated with additional risk if the asphyxial process progresses too far in utero? Are there other ways to evaluate fetal risk? We believe the current audit starts to provide answers to these questions.

From our study we would suggest that there is a set deterioration of ultrasonographic characteristics in the fetus exposed to chronic asphyxia. First, the umbilical artery Doppler recording becomes abnormal, then fetal growth is demonstrably retarded, and finally the biophysical profile score becomes abnormal. There are two arguments to support this suggestion. First, an abnormal biophysical profile score was never encountered without an abnormal umbilical artery Doppler recording and low abdominal circumference, and an abnormal biophysical profile score and a low abdominal circumference were never found without an abnormal umbilical artery Doppler recording, yet an abnormal umbilical artery Doppler recording could be found in isolation. Second, progressive deterioration in the ultrasonographic characteristics in the suggested order was found in practice: 15 of 22 fetuses with an abnormal umbilical artery Doppler recording subsequently manifested a low abdominal circumference and two of these 15 eventually also had an abnormal biophysical profile score; 17 of 33 fetuses with an abnormal umbilical artery Doppler recording and low abdominal circumference subsequently had an abnormal biophysical profile score. The time scale of this deterioration was extremely variable, which further complicates management. In addition to the suggested order of deterioration of the three ultrasonographic characteristics, we speculate that when the biophysical profile scores becomes abnormal it also does so in a set order, with the NST and fetal breathing being early signs to be lost, then fetal movement and fetal tone.[15] Because fetal breathing is periodic,[16] the deterioration of the NST may be the more valuable early warning sign. In our experience severe oligohydramnios with an amniotic fluid volume <10 mm was a relatively rare and presumably late occurrence. This is at variance with the findings of some other workers,[15] although some of this apparent discrepancy may be explained by differences in definitions of oligohydramnios. For example, five cases in group D and 10 cases in group E had amniotic fluid pools that were between 10 to 19 mm (inclusive). However, we would contend that severe reduction in volume might be a late event because the incidence of renal failure in such babies after birth is relatively rare (Tables IV and V). Although moderate oligohydramnios (amniotic fluid volume 10 to 19 mm) reflects the severity of the intrauterine pathologic condition, we are

of the opinion that severe oligohydramnios (amniotic fluid volume <10 mm) should remain our definition of choice for the biophysical profile score. Adopting a definition of <20 mm is likely to increase the incidence of abnormal biophysical profile score and, in turn, the incidence of preterm deliveries, with a major effect on outcome (Tables IV, V, and VI). The use of the three characteristics in combination appeared to provide a useful guide to fetal risk. If all three were normal or if an abnormal umbilical artery Doppler recording alone or a low abdominal circumference alone were the only abnormality (groups A, B, and C), the prognosis for the fetus was excellent. The majority of the mortality and morbidity was found in groups D and E, with group E fetuses tending to have the worse prognosis of the two groups. However, the question of whether this difference in outcome between groups D and E is due to a more advanced asphyxial process in utero (as indicated by the development of an abnormal biophysical profile score) in addition to the differences in preterm delivery rates is not fully resolved by this review. We would argue that there is some evidence of an effect from a more advanced asphyxial process in group E in that in the cohorts of fetuses from groups D and E matched for gestation, the severe complications (those leading to death—respiratory distress syndrome resulting in bronchopulmonary dysplasia, intraventricular hemorrhage, necrotizing enterocolitis, and neurologic abnormality) were exclusively found in group E (Table VI). Nevertheless, the incidence of other complications was not statistically different in group E. Recruitment of large numbers is required for clarification of this issue.

From our experience we would suggest modifications

Table VI. Fetal outcome of matched cohort with and without abnormal biophysical profile score

Characteristic	*Subgroup*	
	D: Umbilical artery Doppler recording abnormal plus low abdominal circumference (n = 14)	*E: Umbilical artery Doppler recording abnormal plus low abdominal circumference plus biophysical profile score <8 (n = 14)*
Gestation at delivery (median and range)	35 (27-39)	35 (27-39)
Preterm (No.)	11	11
Survived 4 wk	14 100%)	12 (85.7%)

to our fetal assessment protocol for pregnancies referred to the Fetal Assessment Unit because of hypertension or SGA.

Hypertension alone and normal ultrasonographic characteristics. There is a small risk (8%) of these fetuses having a raised pulsatility index at 9 to 12 days after presentation. The severity of the maternal condition is likely to be the indication for delivery. The fetal prognosis is very good with the main risk being preterm delivery. We consider that the aims of management should be, first, to control the maternal blood pressure to prolong the pregnancy and avoid preterm delivery if possible and, second, to confirm the absence of fetal risk by serial umbilical artery Doppler recording and growth recordings only.

Low abdominal circumference only at presentation. If the abdominal circumference is low and the umbilical artery Doppler recording is normal, then it is likely that the smallness is constitutional or genetic rather than caused by chronic fetal asphyxia. The main risk to the fetus is preterm delivery. Of note, four of the 13 fetuses delivered electively in this group were, in our opinion, unnecessarily delivered preterm because of their small size alone. We consider the appropriate management to be serial monitoring of growth and umbilical artery Doppler recording. In the absence of maternal complications and with normal umbilical artery Doppler recording and growth of the abdominal circumference after the appropriate trajectory, delivery can be deferred until at least 37 weeks.

Abnormal umbilical artery Doppler recording alone at presentation. There is a 75% chance of another ultrasonographic abnormality becoming manifest 14 to 56 days (median 21 days) later. Although the umbilical artery Doppler recording remains the only ultrasonographic abnormality, the prognosis for the fetus remains very good. The aims of management are monitoring fetal growth and biophysical profile score and, if these are normal, avoiding preterm delivery.

Abnormal umbilical artery Doppler recording and low abdominal circumference at presentation. This group is the most difficult to manage. In fetuses with these two ultrasonographic abnormalities there is a 39.6% risk of the subsequent development of an abnormal biophysical profile score 1 to 26 days (median 7 days) later. Although an abnormal biophysical profile

score will therefore not develop in the majority of the fetuses, once it becomes abnormal, it may be associated with a worse outcome. Should we deliver more preterm or wait until the biophysical profile score becomes abnormal? We believe that the issue can be resolved only by a multicenter randomized trial. However, in the meantime a pragmatic approach to management is necessary. Careful ultrasonographic examination of the fetus should be carried out to exclude the stigmas of chromosome abnormality.[17] In this context it is noteworthy that both cases of chromosomal abnormality in our study had unusually large amniotic fluid volumes of 75 and 90 mm, respectively. However, even if the result of ultrasonographic examination is apparently normal, fetal karyotyping should be considered. Preeclampsia in the mother does not exclude a chromosomal anomaly. In both pregnancies with fetal trisomy 18 the mother had proteinuric hypertension. We prefer placental biopsy for karyotyping because we can obtain a result on the same day, compared with 2 days for fetal blood, during which time the fetal condition may deteriorate.[9]

Our opinion is that we should deliver the fetus that is morphologically normal with an abnormal umbilical artery Doppler recording and a low abdominal circumference at ≥34 weeks rather than wait for an abnormal biophysical profile score to develop. Perhaps this limit should be reduced to 32 weeks. Between 28 and 32 weeks steroids should be given and frequent (daily?) biophysical profile scores determined. At the first sign of biophysical profile score deterioration (probably manifest as an unreactive NST with decelerations) delivery should be undertaken. Fetal size should not be used as a major influence on this decision. Before 28 weeks we would favor biophysical profile score monitoring and the administration of steroids but would also consider delivery with persistent abnormality of the whole biophysical profile score on prolonged (60-minute) testing.

The audit did not set out to address the long-term outlook for the babies. However, development of the appropriate management strategy for fetuses with abnormal umbilical artery Doppler recording and low abdominal circumference also depends on information on the long-term neurodevelopmental progress through infancy and childhood of babies from group D compared with those from group E delivered at a similar gestational age.

Abnormalities of all three characteristics at presentation. Once an abnormal biophysical profile score has developed, there is the greatest risk of morbidity and mortality (Tables IV and V). Although this risk is largely influenced by gestation there is a suggestion of an effect from a more advanced asphyxial process in utero. With an abnormal biophysical profile score the approach to management should be positive because, in our experience, 75% of all fetuses with an abnormal biophysical profile score survived and one in 10 had no problems at all in the newborn period. Even when the biophysical profile score was abnormal at presentation, there was a 55.6% chance of survival. If structural abnormality can be excluded by ultrasonography, then delivery should be expedited. This should probably be by cesarean section because attempts at vaginal delivery are likely to be complicated by fetal distress in labor and birth asphyxia necessitating resuscitation (Table IV).

Finally, this study has implications for neonatal management. The comprehensive fetal assessment identifies a group more likely to require expert neonatal resuscitation and management of respiratory distress syndrome.[18, 19] In addition, necrotizing enterocolitis only occurred in babies delivered with a preceding abnormal umbilical artery Doppler recording, low abdominal circumference, and poor biophysical profile score. The incidence and severity of this condition may be reduced if introduction of oral food is delayed and if prophylactic antibiotics are used, although these questions also will require multicenter trials for answers.

A model-based prediction for transvaginal ultrasonographic identification of early intrauterine pregnancy

Bruce S. Shapiro, MD,[a] Michael Escobar, PhD,[b] Robert Makuch, PhD,[b] Gad Lavy, MD,[a] and Alan H. DeCherney, MD[a]

New Haven, Connecticut

OBJECTIVE: Our objective was to develop a mathematic model for the prediction of transvaginal ultrasonographic identification of intrauterine gestation as a function of human chorionic gonadotropin titer or gestational age.

STUDY DESIGN: In this prospective, descriptive study normal intrauterine pregnancies of 31 patients from the Yale in vitro fertilization and embryo transfer program and infertility clinic were studied. Logistic regression analysis was used to develop a probability curve of transvaginal ultrasonographic detection of intrauterine pregnancy as a function of human chorionic gonadotropin titer or gestational age with a 5 MHz vaginal transducer.

RESULTS: A model-based prediction was constructed. It revealed that nearly all intrauterine sacs should be identified by a human chorionic gonadotropin titer of 3000 mIU/ml (first international reference preparation) or by a gestational age of 37 days on the basis of the 5 MHz vaginal transducer.

CONCLUSIONS: A model-based prediction for transvaginal ultrasonographic identification of early intrauterine pregnancy is presented that can be readily adapted by individual institutions using their own ultrasonographic equipment and human chorionic gonadotropin assay. (AM J OBSTET GYNECOL 1992;166:1495-500.)

Key words: Transvaginal ultrasonography, mathematic model, early pregnancy

The widespread availability of a radioimmunoassay for human chorionic gonadotropin furnished the clinician with the ability to make an early diagnosis of pregnancy. The development of high-resolution abdominal ultrasonography provided the clinician with the opportunity to make the early diagnosis of intrauterine gestation. The major clinical importance of this advance was in the early exclusion of ectopic pregnancy. The confirmation of an intrauterine pregnancy is considered sufficient to exclude ectopic gestation because hetertotopic pregnancy is relatively uncommon.[1-4]

The absence of an identifiable intrauterine gestational sac on abdominal and transvaginal ultrasonographic examination when the human chorionic gonadotropin titer has reached a defined threshold level has been used widely as a criteria for surgical explo-

From the Department of Obstetrics and Gynecology[a] and the Division of Biostatistics,[b] Yale University School of Medicine.

ration with the provisional diagnosis of ectopic pregnancy. The threshold level of human chorionic gonadotropin above which an intrauterine gestational sac is expected in a normal pregnancy by abdominal ultrasonography was initially characterized to occur at a human chorionic gonadotropin titer of ≥6500 mIU/ml, by means of the first international reference preparation.[5, 6] More recent reports have suggested an even lower threshold by abdominal ultrasonography, with intrauterine gestational sacs identified above 1800 mIU/ml, as determined by the second international standard, which was considered roughly equivalent to 3600 mIU/ml by the first international reference preparation.[7] A majority of patients with ectopic gestation, however, have titers below even the lower of these levels, and the identification of an intrauterine gestation would thus not be expected.[7] The ability to make an earlier diagnosis of ectopic pregnancy would therefore be enhanced if the threshold level for reliable detection of an intrauterine gestation were lower.

The transvaginal ultrasonographic approach has been used extensively for follicular monitoring during ovulation induction in programs of in vitro fertilization where it has been found to provide both increased visualization of the pelvis and better resolution than the transabdominal approach.[8] Furthermore, recent data have demonstrated the enhanced ability of the transvaginal approach in visualizing the gestational sac of early pregnancy whether intrauterine or extrauterine at an even earlier gestational age than reported with the transabdominal approach.[9-19] Initially these latter studies focused on the earliest possible detection of an intrauterine gestational sac and relied on several estimations to determine the point at which an intrauterine gestational sac should be expected. The ability to determine the maximal human chorionic gonadotropin titer or day of gestation when an intrauterine gestation should be reliably detected is the parameter of most clinical importance.

The purpose of the current study was to determine the human chorionic gonadotropin titer and gestational age at which the appearance of an intrauterine gestational sac can be expected to be identified by transvaginal untrasonographic examination in a viable, singleton intrauterine pregnancy on the basis of a 5 MHz transvaginal probe. A method is described that can be adapted by individual institutions to determine the probability of sac identification at a specific human chorionic gonadotropin titer or gestational age with the respective institution's ultrasonographic equipment and human chorionic gonadotropin assay.

Material and methods

Patients in the Yale in vitro fertilization and embryo transfer program and other patients in the infertility clinic were enrolled in the study immediately on confirmation of pregnancy by positive serum human chorionic gonadotropin titers. Patients who subsequently were verified to have normal, singleton intrauterine gestations were used for the calculations. There were eight patients from the in vitro fertilization and embryo transfer program, 17 patients who underwent ovulation induction with menotropins, and six patients with spontaneous pregnancies. Serum human chorionic gonadotropin titers were measured in samples drawn on the day of ultrasonographic examination; they were determined by an immunoradiometric assay and a double-antibody technique with the first international reference preparation as a reference standard, the details of which have been previously described.[5, 6, 9] The day of gestation was calculated from the day of human chorionic gonadotropin injection. Gestational age data were used only from in vitro fertilization patients and those undergoing ovulation induction who received human chorionic gonadotropin for initiation of ovulation.

The patients were then examined with transvaginal ultrasonography usually at 1- to 4-day intervals as determined by patient availability. The ultrasonographic examinations were performed using a model RT 3000 General Electric ultrasound machine (Rancho Cordova, Calif.) and a 5 MHz vaginal transducer. All examinations were performed in real time in a routine, systematic manner with each study including both transverse and longitudinal scans. All examinations and interpretations were completed by a single observer (B.S.S.) independent of the patient's human chorionic gonadotropin titer at the time of each examination. Thus patients were monitored with serial ultrasonographic examinations to determine the highest titer or gestational age at which an intrauterine sac was not identified and then the point at which it was subsequently identified by ultrasonography.

Statistical analysis to calculate the probability of gestational sac appearance as a function of human chorionic gonadotropin titer was performed by both nonparametric and parametric methods with an interval censoring technique[20, 21] and logistic regression analysis, respectively. A probability curve for the detection of an intrauterine sac at each human chorionic gonadotropin titer and gestational age was then constructed from the logistic regression curve.

Results

In this study group the lowest titer of human chorionic gonadotropin at which an amniotic sac was identified occurred at a level of 912 mIU/ml (first international reference preparation). The highest titer at which a sac was not detected but was subsequently identified occurred at a titer of 2550 mIU/ml (first international reference preparation). There was an overlap

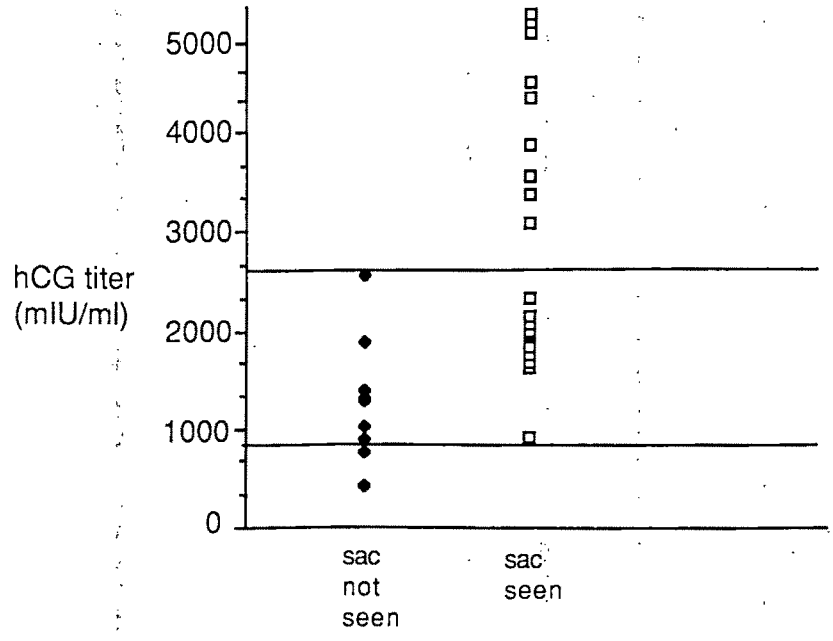

Fig. 1. Human chorionic gonadotropin titers at which sacs may or may not be identified from 912 to 2550 mIU/ml.

of human chorionic gonadotropin titers at which sacs may or may not have been identified between 912 and 2550 mIU/ml (first international reference preparation) (Fig. 1). When determined by gestational age, the highest titer at which a sac was not detected but subsequently identified occurred on cycle day 34, with the earliest detection of a sac occurring on day 31. Between these two points there was also an overlap of gestational ages during which time an intrauterine pregnancy may or may not have been identified.

A probability curve for intrauterine gestational sac identification was constructed with the logistic regression model as a function of both human chorionic gonadotropin titer (Fig. 2) and gestational age (Fig. 3). The step function corresponds to the observed probability of sac identification derived from the data, whereas the smoothed curve represents the model-based probability of sac identification, which is described by the function $y = 1/1 + \exp [\beta 0 + \beta 1 \ln (\text{human chorionic gonadotropin})]$, where y = probability of appearance as a function of the human chorionic gonadotropin titer, $\beta 0 = 41.78$, and $\beta 1 = -5.64$. With x^2 used as a measure for the fitness of the curve, $\chi^2 = 12.55$ and $p < 0.001$. Similarly, the model-based probability for sac identification as a function of gestational age is described by the function $y = 1/1 + \exp [\beta 0 + \beta 1 (\text{days})]$, where y = probability of appearance as a function of the gestational age in days, $\beta 0 = 12.35$ and $\beta 1 = -0.60$. With χ^2 used for measuring the fitness of the curve, $\chi^2 = 8.1$ and $p = 0.004$. From these curves it can be seen that 50% of the gestational sacs could be identified by a human chorionic gonadotropin titer of 1500 mIU/ml (first international reference preparation) or at a gestational age of 32 to 33 days in a normalized 28-day cycle. Furthermore, from the logistic regression model it can be seen that nearly all intrauterine sacs should be identified by a human chorionic gonadotropin titer of 3000 mIU/ml (first international reference preparation) or by a gestational age of 37 days in a singleton intrauterine pregnancy when the 5 MHz vaginal transducer described is used.

Although the highest titer without identification of an intrauterine gestation occurred at a human chorionic gonadotropin titer of 2550 mIU/ml (first international reference preparation) and by a gestational age of 34 days, the model predicts somewhat higher values at which nearly all of the sacs should be identified. This is explained by the fact that the model takes into account the inherent variability of future measurements.

Comment

The concept of a discriminatory zone was originally established to determine human chorionic gonadotropin titers at which an intrauterine sac should be seen.[5] Early reports have revealed earlier detection in the evaluation of intrauterine pregnancy with the transvaginal approach than those reported with transabdominal ultrasonograhpy.[10, 11] These studies reported ranges of human chorionic gonadotropin titers at which intrauterine pregnancies could be identified, but, because

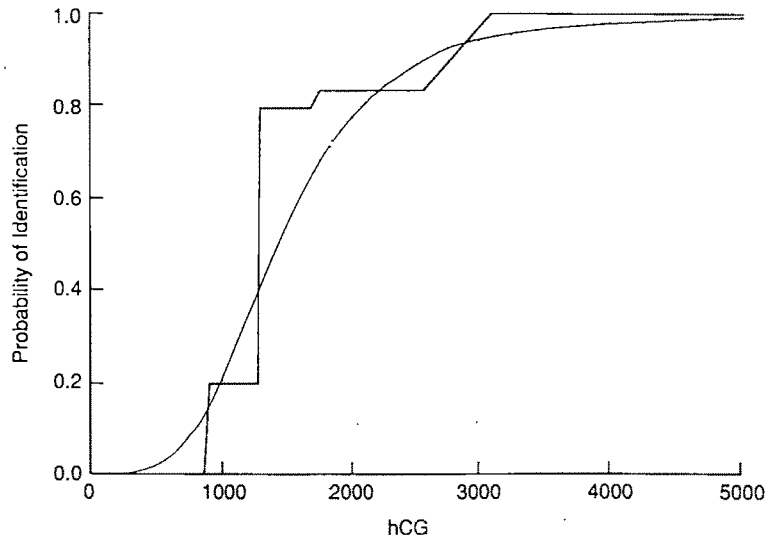

Fig. 2. Model-based probability curve for intrauterine gestational sac identification by human chorionic gonadotropin titer.

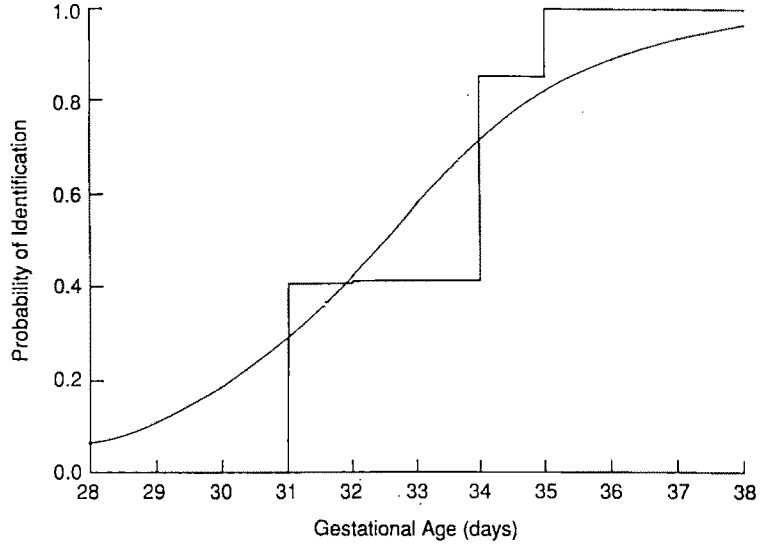

Fig. 3. Model-based probability curve for intrauterine gestational sac identification by gestational age normalized to a 28-day cycle.

the major importance of ultrasonographic identification is in knowing when an intrauterine gestational sac should be identified, reporting the range of human chorionic gonadotropin titers at which intrauterine pregnancies could be identified is of little direct help to the clinician. Furthermore, reporting only the range together with the minimum and maximum values at which intrauterine sacs are identified can be misleading because of an inaccurate representation of the true statistical distribution at which points identification may or may not occur. The latter is true because ultrasonographic identification of the intrauterine gestational sac represents a skewed, long-tailed statistical distribution. At the extreme end of the distribution, represented by either the titers or gestational age, the highest titers or oldest gestational ages at which sacs cannot be identified become progressively smaller, whereas the number of sacs identified in this range becomes progressively larger. The use of minimum and maximum values as summary statistics fails to provide information about the probability of appearance within a given range of either titer or gestational age of sac identifi-

cation and thus overlooks the most important facet of this type of study, which is to determine the probability of sac identification at any specific titer or gestational age. Futhermore, when the sample size is neglected in the determination of expected sac identification, an inaccurate representation of the points at which sacs are identified occurs at the extreme end of the distribution curve for identification, giving the appearance of an exact point above which all sacs should be identified. With the use of a mathematic model and interval censoring techniques, as well as the incorporation of sample size into the calculation, such as in a logistic regression model, the specific likelihood of identification can be calculated as a function of either human chorionic gonadotropin titer or gestational age. The clinician can therefore know the likelihood of sac identification at a particular human chorionic gonadotropin titer or gestational age. Thus, for example, at a human chorionic gonadotropin titer of 1500 mIU/ml (first international reference preparation) or between 32 and 33 days' gestation, 50% of the sacs should be visualized and 50% will not be visualized in a normal singleton intrauterine pregnancy in the current study.

It should be noted that the maximum values observed in a sample of the population are always going to be less than or equal to the actual maximum values, and conversely the minimum values observed are always greater than or equal to the actual minimum values in the true population. Thus, as more data are accumulated with the same transvaginal probe, the detection of an intrauterine gestational sac will be reported at successively lower titers and earlier gestational ages, whereas the highest titer and gestational age at which all sacs are identified will become progressively greater. The latter result will tend to be mitigated, however, with the use of transvaginal probes having greater resolution, so that the size and the gestational age at which most of the sacs are identified may be lower overall. Recent studies have attempted to describe mathematically the correlation of human chorionic gonadotropin titer and sac size with simple regression analysis correlating sac size with human chorionic gonadotropin levels to determine a threshold point of human chorionic gonadotropin titer at which a sac should be seen.[12, 14, 18] However, these studies have failed to address the limitations imposed by extrapolating to the general population threshold values determined from the study of a specific sample size. In the current study the authors have constructed a model-based prediction with logistic regression analysis to predict the probability of seeing a sac at a selected value of human chorionic gonadotropin or a selected gestational age that incorporates the sample size into the calculation.

Athough the identification of the gestational sac may be expected at the limits of resolution of the equipment, this merely represents the theoretic limits of detection. Biologic variability in singleton gestations and the possibility of inflated serum human chorionic gonadotropin values from multiple gestations must be considered in the routine clinical use of these data. Furthermore, other confounders are possible when such small sacs are viewed. The presence of small amounts of fluid such as blood can easily be mistaken for a sac in the presence of decidualized endometrium. Thus the presence of the pseudosac in ectopic pregnancy may also be difficult to distinguish from an early pregnancy. For these reasons, although the identification of an intrauterine sac is reassuring, it is important to correlate the findings with serial human chorionic gonadotropin titers and serial examinations.

Influence of labor and oxytocin on in vitro leukotriene release by human fetal membranes and uterine decidua at term gestation

Nino Pasetto, MD,[a] Alessandra Zicari, MD,[b] Emilio Piccione, MD,[a] Luisa Lenti, MD,[b] Giuseppe Pontieri, MD,[b] and Carlo Ticconi, MD[a]

Rome, Italy

OBJECTIVE: The purpose of this study was to determine whether labor and oxytocin influence in vitro leukotriene release by human fetal membranes and uterine decidua at term gestation.
STUDY DESIGN: All women ($N = 27$) were studied in an academic clinical research environment. They were delivered either vaginally or before labor by cesarean section. Tissues were incubated with calcium ionophore A23187 alone or with calcium ionophore A23187 after preincubation with either oxytocin, BW755c, or cycloheximide. Leukotrienes in culture medium were determined by high-performance liquid chromatography. Statistical analysis was performed with analysis of variance.
RESULTS: Tissues obtained after vaginal delivery released significantly higher ($p < 0.05$) quantities of leukotrienes LTB_4, LTD_4, and Δ-6-trans-LTB_4 than did tissues obtained during cesarean section. Leukotriene release was stimulated by oxytocin and was inhibited by both BW755c and cycloheximide.
CONCLUSION: These results suggest an activation of the arachidonate lipoxygenase pathway in these tissues during labor. Oxytocin could play a regulatory role in this process. (Am J Obstet Gynecol 1992;166:1500-6.)

Key words: Leukotrienes, human fetal membranes, oxytocin, parturition

The role of cyclooxygenase derivatives of arachidonic acid in the biochemical events leading to human labor has been extensively investigated.[1] There is a consensus that prostaglandins PGE_2 and $PGF_{2\alpha}$ are involved both in myometrial contractions and in the ripening of the uterine cervix.[2, 3] The hormonal factor(s) regulating prostaglandin production in labor have not been fully elucidated.

In contrast, little is known about the lipoxygenase derivatives of arachidonic acid in labor. The leukotrienes have potent biologic actions in nonreproductive tissues.[4] Recent studies suggest that leukotrienes could play a role in the biochemical processes of labor in the human[5-7] and in the nonhuman primate.[8]

This study was undertaken to examine the in vitro release of leukotrienes by human fetal membranes and uterine decidua, to verify whether differences in the production of these substances could be detected in relation to the presence or absence of labor, and to investigate whether oxytocin could stimulate leuko-

triene synthesis and release by these tissues. This role for oxytocin could be suggested because it has been previously shown that oxytocin induces an increased release of cyclooxygenase arachidonate metabolites by human decidua at term gestation.[9]

Material and methods

Subjects. Twenty-one healthy women (age range 24 to 32 years) were included in the study. These patients had singleton uncomplicated pregnancies at term. They were divided into three groups: Group 1 included seven women who were delivered vaginally after spontaneous labor without medication until after delivery; groups 2 and 3 each included seven women who were delivered by elective repeat cesarean section before labor. All patients who underwent cesarean section received a general anesthetic (atropine sulfate 0.02 mg/kg, thiopental sodium 4 mg/kg, pancuronium bromide 0.08 mg/kg, nitric oxide 60% plus oxygen 40%) until the fetus was delivered.

Gestational age, which was calculated by the date of the last menstrual period and was confirmed by ultrasonographic examination, was comparable in the three groups. Birth weights and Apgar scores were also comparable.

Sample collection and tissue culture. Reflected fetal membranes with adherent decidua were obtained after spontaneous vaginal delivery (group 1) and during repeat cesarean section before labor (groups 2 and 3).

Specimens were placed in ice-cold sterile saline solution and were immediately sent to the laboratory for processing. All specimens were processed as soon as they reached the laboratory.

Tissues were layered on Petri dishes supported by ice and were washed several times with ice-cold sterile culture medium M199 (Gibco, Grand Island, N.Y.) to remove blood. Clots were carefully and gently removed with fine forceps, and additional washing completely removed blood. Tissues were cut with fine scissors into disks. The areas in which the amnion was partially detached from the chorion were discarded. Tissues were quantified by wet weight, were placed in Petri dishes containing 5 ml of culture medium M199 and were incubated at 37° C in an atmosphere of 95% oxygen and 5% carbon dioxide.

Samples obtained from subjects of groups 1 and 2 were divided into three specimens. They were incubated in the presence of the calcium ionophore A23187 (Sigma Chemical Co., St. Louis), 10 μmol/L. Previous time course analysis, which had been carried out at 30, 60, and 90 minutes of incubation, had demonstrated maximum leukotriene release after 60 minutes of incubation with ionophore A23187. For this reason all subsequent experiments were carried out at 60 minutes of incubation.

The samples were preincubated for 30 minutes with 40 mIU oxytocin (Syntocinon; Sandoz, Basel). At the end of the preincubation period, tissues were washed twice with fresh medium and then incubated for an additional 60-minute period in the presence of the calcium ionophore A23187, 10 μmol/L. Control samples were incubated without calcium ionophore.

Tissues obtained from the subjects of group 3 were preincubated 30 minutes at 37° C with oxytocin at four different concentrations (10, 20, 40, and 60 mIU/ml) and treated as described previously. Tissue viability, judged by the lactic dehydrogenase assay,[10] was 89% ± 4% before incubation and 80% ± 3% at the end of the incubation. No difference was found in tissue viability between samples obtained after cesarean section before labor and those obtained after spontaneous delivery.

To verify whether leukotriene release into the culture medium was due to active secretion and not to our experimental manipulations, we performed additional experiments in which some specimens from group 1 were coincubated either with 0.5 μg/ml cycloheximide (Sigma) or with BW755c (Wellcome Research Laboratories), 100 μmol/L, for 15 minutes and then challenged with 10 μmol/L calcium ionophore. Culture medium from every experiment was collected, centrifuged at 1800 rpm for 15 minutes to eliminate cell debris, and stored at −80° C until the successive assay was undertaken.

Analysis of leukotrienes. We used Powell's modified method, described in detail elsewhere,[7] for leukotriene extraction.

Dried fractions obtained after extraction were resuspended in 100 μl methanol and filtered. The clear solution was applied to an Ultrasphere C18 column (5 μm particle size; Beckman Instruments, Inc., Bioanalytical Systems Group, San Ramon, Calif.) with methanol/water/acetic acid (73:27:0.1), pH adjusted to 4.7 with ammonium hydroxide, used as the mobile phase. A flow rate of 1 ml/min was maintained, and the effluent was monitored at 280 nm with an LC 95 Perkin Elmer Detector and a Perkin Elmer 235 Diode Array Detector to obtain ultraviolet spectra, absorbance maxima, and purity indexes. Retention times were calculated by coelution with authentic standards. The peak areas or heights were calculated with an LCI 100 Laboratory Computing Integrator (Perkin Elmer). Standard curves of the individual leukotrienes were obtained with five different concentrations (1.5625 to 25 ng) and showed the following correlations: For LTB_4, $r = 0.978$ and $y = 56.224 \pm 53.59x$; for LTD_4, $r = 0.945$ and $y = 18.54 \pm 13.28x$; for Δ-6-trans-LTB_4, $r = 0.983$ and $y = 116.8 \pm 51.28x$. The minimum detectable quantities were 1.5 ng for LTD_4 and 1.0 ng for LTB_4 and for Δ-6-trans-LTB_4.

Leukotriene recovery was calculated by adding a known amount to 1 ml of culture medium and pro-

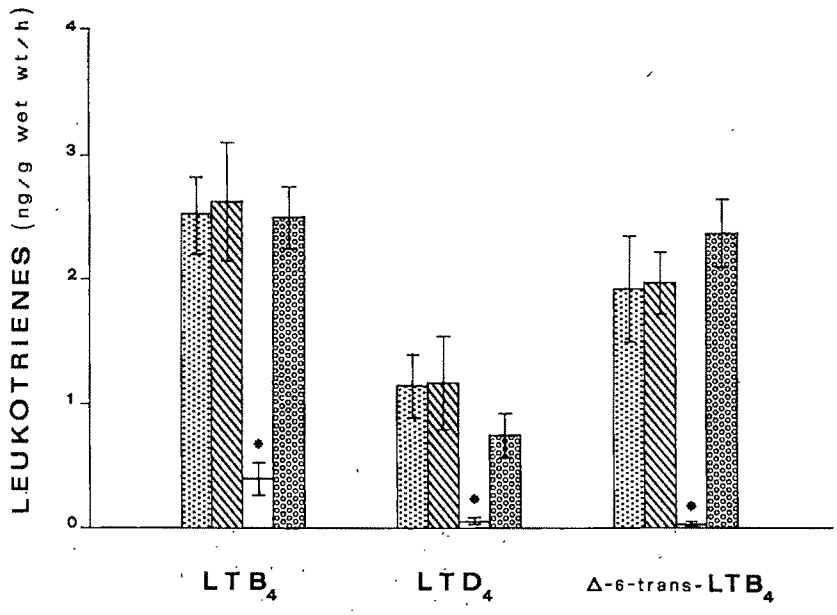

Fig. 1. Leukotriene release by human fetal membranes and uterine decidua at term gestation. Group 1: Tissues were obtained after spontaneous delivery. They were either incubated with calcium ionophore A23187 10 μmol/L for 60 minutes (▨, $n = 7$) or preincubated for 30 minutes with oxytocin 40 mIU/ml, washed, and then incubated for 60 minutes with calcium ionophore A23187, 10 μmol/L (▧, $n = 7$). Group 2: Tissues were obtained during elective cesarean section before labor. They were either incubated with calcium ionophore A23187, 10 μmol/L for 60 minutes (□, $n = 7$) or preincubated for 30 minutes with 40 mIU/ml oxytocin, washed, and then incubated for 60 minutes with calcium ionophore A23187, 10 μmol/L (▩, $n = 7$). Values are presented as means ± SD. Analysis of variance: $F = 19.19$, $p < 0.01$ for LTB_4; $F = 7.79$, $p < 0.01$ for LTD_4; $F = 23.47$, $p < 0.01$ for Δ-6-trans-LTB_4. *Asterisk,* Significantly lower ($p < 0.05$) than other means for each eicosanoid (Student–Newman-Keuls test).

cessing these samples as previously reported. Final recovery averaged 60% ± 5% for LTD_4 and 75% ± 6% for LTB_4 and Δ-6-trans-LTB_4.

The sensitivity of the assay for LTB_4 at 270 nm ($\epsilon = 50.000$) is 100 pg, for Δ-6-trans-LTB_4 at 270 nm ($\epsilon = 56.000$), 80 pg, and for LTD_4 at 280 nm ($\epsilon = 40.000$), 1 ng when the detector is set at 0 001 AUFS (absorbance units full scale). For LTB_4 the intraassay coefficient of variation is 4% and the interassay coefficient of variation is 3%. For LTD_4 the intraassay coefficient of variation is 5% and the interassay coefficient of variation is 8%. For Δ-6-trans-LTB_4 the intraassay coefficient of variation is 6% and the interassay coefficient of variation is 7%.

Statistical analysis. Data are presented as means ± SD. Statistical analysis was performed with a one-way analysis of variance. The Student–Newman-Keuls test was used for post hoc multiple comparisons among groups.

Results

After incubation with calcium ionophore A23187 10 μmol/L, tissues obtained after spontaneous labor released LTB_4 (2.53 ± 0.67 ng/gm wet weight per hour), LTD_4 (1.16 ± 0.58 ng/gm wet weight per hour), and Δ-6-trans-LTB_4 (1.92 ± 0.88 ng/gm wet weight per hour) into the culture medium in significantly higher amounts than did tissues obtained after elective cesarean section before labor (group 2: LTB_4, 0.40 ± 0.27 ng/gm wet weight per hour; LTD_4, 0.038 ± 0.016 ng/gm wet weight per hour; Δ-6-trans-LTB_4, nondetectable amount) (Figs. 1 and 2).

Tissues incubated in the absence of calcium ionophore (controls) released into the culture medium only minimal amounts of the previously mentioned leukotrienes, regardless of the presence or absence of labor (LTB_4, 0.11 ± 0.06 ng/gm wet weight per hour; LTD_4 and Δ-6-trans-LTB_4, nondetectable amounts).

Preincubation with oxytocin greatly increased the release into the culture medium of leukotrienes by tissues obtained in the absence of labor (LTB_4, 2.51 ± 0.47 ng/gm wet weight per hour; LTD_4, 0.73 ± 0.35 ng/gm wet weight per hour; Δ-6-trans-LTB_4, 2.37 ± 0.58 ng/gm wet weight per hour) (Figs. 1 and 2). This increase of the synthesis and release of the previously mentioned leukotrienes was statistically significant

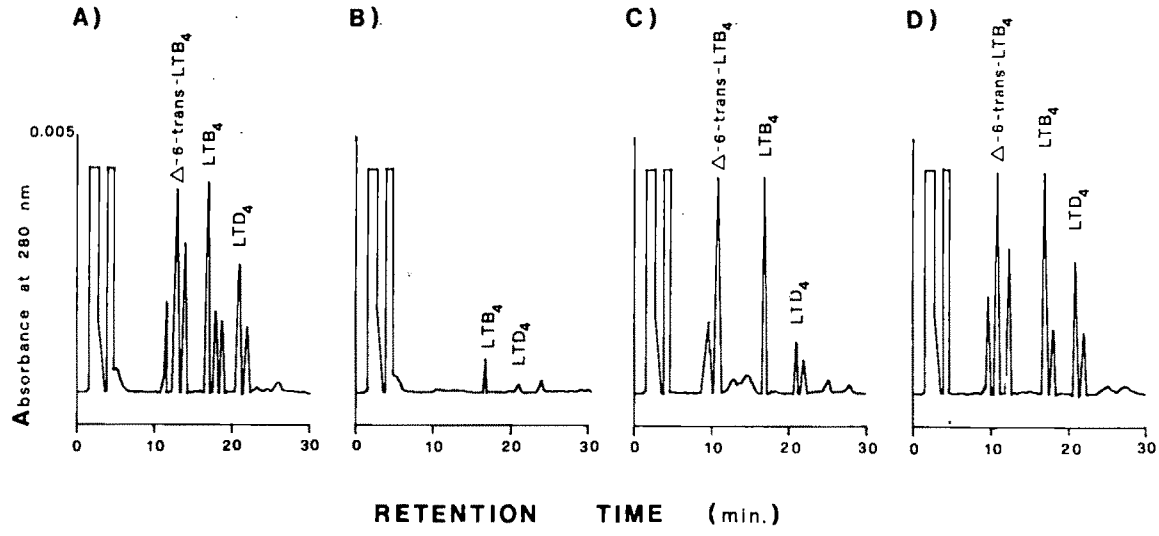

Fig. 2. Chromatographic patterns representative of culture media of human fetal membranes and uterine decidua. *A*, Vaginal delivery plus 10 μmol/L calcium ionophore A23187; *B*, cesarean section plus 10 μmol/L calcium ionophore A23187; *C*, cesarean section plus 40 mIU/ml of oxytocin plus 10 μmol/L calcium ionophore A23187; *D*, vaginal delivery plus 40 mIU/ml oxytocin plus 10 μmol/L calcium ionophore A23187. Retention times were 13, 17, and 21 minutes for Δ-6-trans-LTB_4, LTB_4, and LTD_4, respectively. Absorbance was determined at 280 nm. Attenuation setting of ultraviolet spectrophotometric detector was 0.005 AUFS.

when compared with the release by tissues obtained in absence of labor and treated only with calcium ionophore. However, when oxytocin was added to the incubation medium of tissues obtained after spontaneous labor, no additional increase of the leukotriene release was detected (LTB_4, 2.62 ± 0.98 ng/gm wet weight per hour; LTD_4, 1.18 ± 0.77 ng/gm wet weight per hour; Δ-6-trans-LTB_4, 1.97 ± 0.47 ng/gm wet weight per hour). Oxytocin stimulated leukotriene release by tissues obtained in the absence of labor in a dose-dependent fashion, the maximum effect occurred at a concentration of 40 mIU/ml (Fig. 3). Thereafter, leukotriene release by tissues markedly decreased.

Addition to culture medium of 0.5 μmol/ml of cycloheximide resulted in a marked decrease of the synthesis and release of leukotrienes by tissues obtained from subjects of group 1. This indicated that we had measured the de novo synthesis rather than a passive release of leukotrienes. The release of LTB_4 (0.85 ± 0.15 ng/gm wet weight per hour), LTD_4 (0.12 ± 0.05 ng/gm wet weight per hour), and Δ-6-trans-LTB_4 (0.015 ± 0.011 ng/gm wet weight per hour) was equivalent to mean percentage decrements of 66.40%, 89.65%, and 99.21%, respectively.

Similarly, the compound BW755c, which is a known inhibitor of both cyclooxygenase and the lipoxygenase enzymes, caused a significant reduction of the release of these compounds (LTB_4, 0.40 ± 0.08 ng/gm wet weight per hour, percentage decrement 84.20%; LTD_4, 0.040 ± 0.012 ng/gm wet weight per hour, percentage decrement 96.56%; Δ-6-trans-LTB_4, 0.520 ± 0.04 ng/gm wet weight per hour, percentage decrement 72.91%) (Fig. 4).

Comment

Our data confirm the ability of human fetal membranes and uterine decidua at term gestation to release leukotrienes in vitro, as was previously described by Rees et al.[11] Those investigators did not find a significant difference in the secretion pattern between unstimulated tissues obtained before and after labor. Results from their study are in accordance with our findings for the secretion patterns of unstimulated tissues. Our control experiments, conducted without calcium ionophore, also indicated that the basal output of LTB_4, LTD_4, and Δ-6-trans-LTB_4 was low and did not significantly change in relation to the presence of labor. These findings would argue against leukotriene production during labor.

However, when calcium ionophore A23187, which stimulates both cyclooxygenase and lipoxygenase enzymes, was added to the culture medium, leukotriene release by tissues obtained after vaginal delivery markedly increased. Confirmation that this increase resulted from an active synthesis was based on the results of

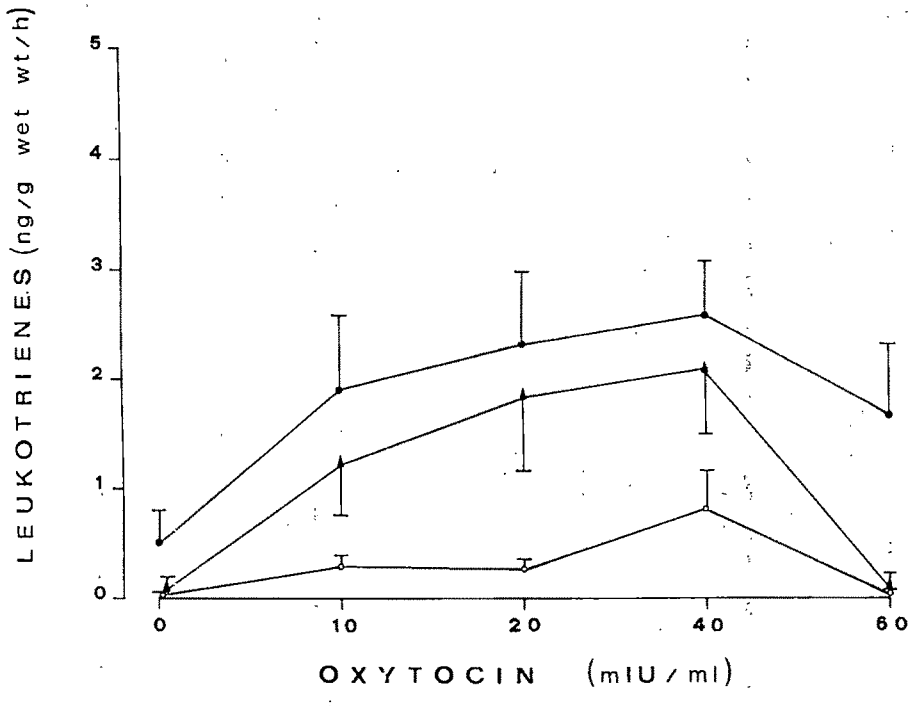

Fig. 3. Concentration-related stimulation of human fetal membranes and uterine decidua leukotriene release by oxytocin. Tissues (n = 7) were obtained during elective cesarean section before labor and were preincubated for 30 minutes with various concentrations of oxytocin, washed and then stimulated for an additional 60-minute period with 10 μmol/L calcium ionophore A23187. ●, LTB_4; ▲, Δ-6-trans-LTB_4; ○, LTD_4.

control experiments performed in the presence of cycloheximide and BW755c, which inhibit protein synthesis and arachidonic acid metabolism enzymes, respectively. The different results obtained between tissues cultured in the absence and in the presence of the calcium ionophore A23187 could be explained by suggesting that in these tissues, 5-lipoxygenase probably shows a low basal activity, and unlike other dioxygenases must be activated to transform arachidonic acid. This behavior of the 5-lipoxygenase is frequently observed in several cells and/or tissues.[12] The finding of an increased leukotriene production by samples obtained after labor and challenged with the calcium ionophore A23187 suggests that in these tissues, a 5-lipoxygenase activity is present and can be activated more easily than in tissues obtained before labor.

Thus it is possible that in human fetal membranes and uterine decidua, both the cyclooxygenase enzyme and the lipoxygenase enzymes are activated during labor. This hypothesis requires further investigation, because it is in some conflict with the initial observations that suggest an inhibition of the arachidonate lipoxygenase pathway[13] or a shift toward cyclooxygenase products during labor.[14] However, it is difficult to compare correctly the results obtained in vitro with different tissue preparations and under different experimental conditions. On the other hand, an activation of arachidonate lipoxygenase in intrauterine tissues during labor has been suggested by the increased amniotic fluid concentrations of LTB_4, the hydroxyeicosatetraenoic acids 12-HETE and 15-HETE,[5] and LTC_4[6] during human labor and of 5-HETE and LTC_4 during rhesus monkey labor.[8]

The results of this study provide evidence that oxytocin significantly stimulates the in vitro release of LTB_4, LTD_4, and Δ-6-trans-LTB_4 by human fetal membranes and uterine decidua at term gestation. This stimulatory effect was exerted at least in part in a dose-dependent fashion and was exerted only on tissues obtained after cesarean section in the absence of labor. In fact, preincubation with oxytocin did not affect the leukotrienes released by tissues obtained after spontaneous labor, probably because the receptors were already saturated by endogenous oxytocin. This assumption is further strengthened by the results of the dose-response oxytocin stimulation curve, in which leukotriene release by tissues markedly decreased at the highest concentration of oxytocin that we used.

By adding oxytocin to the culture systems of tissues taken before labor, we obtained a pattern of in vitro leukotriene release that resembled, quantitatively and qualitatively, that of tissues obtained after spontaneous

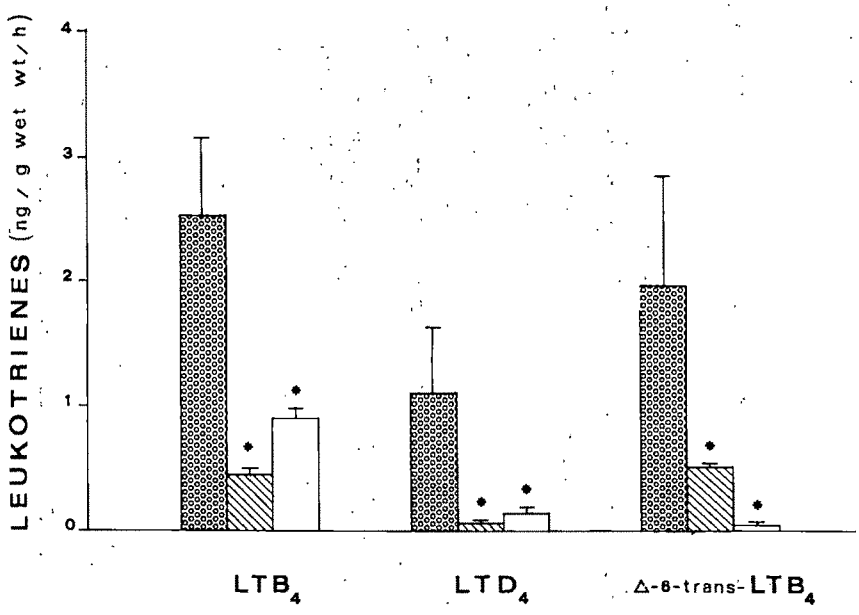

Fig. 4. Effects of BW755c and cycloheximide on leukotriene release by human fetal membranes and uterine decidua obtained after spontaneous labor at term. Tissues were divided into three specimens and treated as follows: They were stimulated for 60 minutes with 10 μmol/L calcium ionophore A23187 (▩); they were preincubated for 20 minutes with 100 μmol/L BW755c, washed, and stimulated for the subsequent 60 minutes with 10 μmol/L calcium ionophore A23187 (▨); they were coincubated with 0.5 μg/ml cycloheximide and 10 μmol/L calcium ionophore A23187 for 60 minutes (□). Data are expressed as nanograms per gram wet weight per hour. Values are the mean of seven different experiments. Analysis of variance: $F = 54.18$, $p < 0.01$ for LTB_4; $F = 25.96$, $p < 0.01$ for LTD_4; $F = 26.03$, $p < 0.01$ for Δ-6-trans-LTB_4. *Asterisk*, Significantly lower ($p < 0.05$) than control for each eicosanoid (Student–Newman-Keuls test).

labor and cultured in the absence of exogenously added oxytocin. What is the significance of this finding? Oxytocin may play a dual role in the mechanism of parturition: It is known to stimulate myometrial contractions by activating myometrial receptors and it may stimulate arachidonic acid metabolism in decidual tissues that possess specific oxytocin-binding sites,[9] which results in the formation of arachidonate lipoxygenase products.

In summary, the results of this study suggest the following conclusions: (1) The fetal membranes and uterine decidua contain an arachidonate lipoxygenase that is presumably present at a low basal activity level; nevertheless, these tissues and the placenta[15] could be an important source of amniotic and fetal circulating leukotrienes during labor; (2) the lipoxygenase activity in the tissues described is more easily inducible during labor and is pharmacologically inducible; (3) labor and oxytocin significantly affect arachidonic acid oxidative metabolism by the lipoxygenase pathway and by the cyclooxygenase pathway in the fetal membranes and uterine decidua.

We thank Professor Scott W. Walsh from the Virginia Commonwealth University, Richmond, Virginia, for useful suggestions, for the revision of the manuscript, and for criticism. We also thank Professor J. Brian Smith from Temple University, Philadelphia, Pennsylvania, for the kind gift of BW755c.

Comparison of adenocarcinoma and squamous cell carcinoma of the uterine cervix: A population-based epidemiologic study

Hoda Anton-Culver, PhD, Jeffrey D. Bloss, MD, Deborah Bringman, MPH, Anna Lee-Feldstein, PhD, Philip DiSaia, MD, and Alberto Manetta, MD

Irvine, California

OBJECTIVE: Our objective was to compare epidemiologic and clinical characteristics of adenocarcinoma with those of squamous cell carcinoma of the cervix, with respect to risk by ethnic group, age at diagnosis, stage of disease at diagnosis, and survival.

STUDY DESIGN: All data were obtained from the Cancer Surveillance Program of Orange County, California, from 1984 through 1989. A total of 152 cases of adenocarcinoma and 457 of squamous cell carcinoma of the uterine cervix were included.

RESULTS: Adenocarcinoma of the cervix was diagnosed at a younger age and an earlier stage than squamous cell carcinoma. Hispanics have the highest risk for squamous cell carcinoma, whereas Asians have the highest risk for adenocarcinoma compared with whites. No differences were observed between the two histologic types in prognosis and survival.

CONCLUSION: Differences between the two histologic types of cervix cancer were found in the age at diagnosis, the extent of disease, and the ethnic distribution. In spite of these differences, prognosis and survival were not affected by histologic type. (Am J Obstet Gynecol 1992;166:1507-14.)

Key words: Adenocarcinoma of the cervix, squamous cell carcinoma of the cervix, ethnic differences, stage at diagnosis, incidence rates

The epidemiologic characteristics and clinical significance of an adenomatous histologic type in carcinoma of the uterine cervix has been the subject of considerable controversy over the past decade. During this time period changes in the incidence of adenocarcinoma of the cervix and in the proportion of cervical cancer patients with an adenomatous histologic type have been reported.[1-9] Several differences in the epidemiologic characteristics between squamous cell carcinoma and adenocarcinoma of the cervix have been shown: (1) age at diagnosis, (2) parity, (3) race, and (4) extent of disease at diagnosis.[1, 3-5, 7] Additionally, the impact of an adenomatous histologic type on the prognosis and survival of women with carcinoma of the uterine cervix has been questioned.[2-4, 6, 7]

In spite of considerable attention to the clinical characteristics of the two histologic types of cervical cancer in the literature, no consistency in conclusions exists. One major reason for the lack of agreement is the difference in methods used in patient selection in these studies. The majority of these reports are based on studies of patients from single institutions, with the use of retrospective data. As a result, they may suffer from selection bias.

The purpose of this cohort study is to determine the epidemiologic and clinical characteristics of adenocarcinoma and to compare them with characteristics of squamous cell carcinoma of the cervix, particularly with respect to population risk by ethnic group, age at diagnosis, stage of disease at diagnosis, and survival.

Material and methods

Study subjects. The current study is based on 678 patients with histologically confirmed invasive cervical cancer diagnosed between 1984 and 1989 and included as a part of a population-based cancer registry, the Cancer Surveillance Program of Orange County. This program is one of 10 regional registries constituting the California cancer reporting system, meeting all reporting requirements of the Surveillance, Epidemiology, and End Results program of the National Cancer Institute. Description of the Cancer Surveillance Program of Orange County and details of data collection methods have been reported previously.[10] Standard data items for each case were abstracted from medical

records and pathology reports. Data quality for the registry is maintained through periodic training programs for hospital registrars and field abstractors, extensive visual and computer editing, and reabstraction of a 10% sample of cases from each facility reporting to the registry.

As a population-based cancer registry the Cancer Surveillance Program of Orange County maintains a cancer information reporting system that includes case reports for all cancer patients seen in every hospital in Orange County and case reports for Orange County resident patients diagnosed or treated for active cancer at hospitals outside the county. Also included are case reports from physicians' offices and other facilities in Orange County, such as clinics where cancer may be diagnosed and treated without hospitalization of the patient. To ensure that all cases of cancer in Orange County residents are included in the Cancer Surveillance Program of Orange County information system, death certificates of county residents with cancer reported as cause of death are matched to case reports on file. Where no case report exists, the source certifying the death is contacted for more information, and a case report is generated for the patient. Non–Orange County residents with diagnosis and treatment in Orange County referral facilities are not included in the patient group under study.

Data taken from Cancer Surveillance Program of Orange County include demographic information (birth date, age, sex, ethnicity, etc.), laboratory data, pathology studies, and stage of disease at time of diagnosis. These data were abstracted from medical and pathology records by trained tumor registrars according to standard procedures.[11] Tumor site and histologic classification were coded according to the International Classification of Diseases for Oncology (ICD-O), published by the World Health Organization.[12]

The 678 individuals studied here with primary invasive cervical cancers include all of the Orange County residents with this malignancy reported to Cancer Surveillance Program of Orange County by April 1991 for the years 1984 through 1989. All cases included in this study were histologically confirmed primary invasive cervical cancers (ICD-O codes 180.0 through 180.9). Specific histology codes were grouped into cell types with World Health Organization specifications for typing of cervical cancer: ICD-O codes 8070 through 8072 and 8076 were grouped as squamous cell carcinoma (457 cases); codes 8140, 8260, 8430, 8441, 8480, 8481, and 8560 were adenocarcinoma (152 cases); other histologic types totaled 69. Among the cases having cancers of other histologic types, there were 42 with either carcinoma, not otherwise specified (ICD-O code 8010) or malignant neoplasm (ICD-O code 8000), and the remaining 27 had cervical cancer of other histologic types (each of those histologic types contained a maximum of four cases). The frequency distribution of cases by histologic type is presented in Table I. Because the current study focuses on the comparison between adenocarcinoma and squamous cell carcinoma, the results presented here include only cases with one of these two histologic types (a total of 609 cases). Patients were also classified as to stage of disease at diagnosis according to the National Cancer Institute and the American College of Surgeons staging system into localized (equivalent to International Federation of Gynecology and Obstetrics stages IA and IB combined), regional (equivalent to International Federation of Gynecology and Obstetrics stages IIA, IIB, IIIA, and IIIB combined), and distant (equivalent to International Federation of Gynecology and Obstetrics stages IVA and IVB combined).

The ethnic distribution for squamous cell carcinoma of the cervix was 302 non-Hispanic whites (66.1%), 100 Hispanics (21.9%), 37 Asians and Pacific Islanders (8.1%), seven blacks (1.5%), and 11 other and unknown (2.4%). For adenocarcinoma the ethnic distribution was 103 non-Hispanic whites (67.8%), 28 Hispanics (18.4%), 17 Asians and Pacific Islanders (11.2%), four other and unknown (2.6%), and no blacks. Because of the small number of cases of black or other and unknown ethnicity, the data by ethnicity will be presented only for non-Hispanic whites, Hispanics, and Asians and Pacific Islanders.

The 1980 population of Orange County reported by the United States Census included 954,000 male residents with a median age of 28.5 years and 979,000

female residents with a median age of 30.5 years. Postcensus figures for Orange County computed by the Forecasting and Analysis Center of the Orange County Administrative Office (Anton-Culver H, et al. University of California, Irvine, unpublished observations) estimated the 1984 population at 2.1 million, which included 73% whites, 17% Hispanics, 7% Asians and Pacific Islanders, and 1% non-Hispanic blacks. The total county population reported by the 1990 census was 2.4 million, 64.5% of whom were whites, 23.4% Hispanics, 10.0% Asians and Pacific Islanders, and 1.6% non-Hispanic blacks.[13]

Analysis. Age-specific incidence rates for cancer of the cervix were calculated with population estimates determined by the Orange County Administrative Offices. Age-adjusted incidence rates were calculated by the direct adjustment method, with the 1970 United States population used as a standard. Statistical analyses were carried out with BMDP[14] and SAS[15] statistical software packages.

Survival of patients with each of two histologic types of invasive cervical cancer, adenocarcinoma and squamous cell, was compared by means of the log rank test[16] as computed with the SAS procedure LIFETEST.[15]

Results

Age-adjusted incidence rates and ethnic groups. The 6-year average age-adjusted incidence rates of squamous cell carcinoma and adenocarcinoma of the cervix by ethnic group are given in Table II. It is clear that for squamous cell carcinoma the risk is higher in both Hispanics and Asians than in non-Hispanic whites (11.2, 9.5, and 5.0 per 100,000 population, respectively). The incidence of adenocarcinoma is highest in Asians and Pacific Islanders, intermediate for Hispanics, and lowest in non-Hispanic whites (4.0, 2.7, and 1.7, respectively).

For all ethnic groups combined the standardized risk ratio comparing age-adjusted incidence rates for squamous cell carcinoma with rates for adenocarcinoma is 3.07. Among both Asians and non-Hispanic whites the standardized risk ratio comparing the age-adjusted incidence rate for squamous cell carcinoma with that of adenocarcinoma is similar (2.4 to 2.9, respectively). The standardized risk ratio comparing squamous cell carcinoma with adenocarcinoma of the cervix among Hispanics (4.2) is numerically greater than in the other two ethnic groups.

Age distribution and age-specific rates by ethnicity. The age-specific rates for squamous cell carcinoma range from 1.66 per 100,000 for the age group 20 to 24 to a maximum of 16.01 per 100,000 at age group 65 to 69. For adenocarcinoma the age-specific incidence rates range from 0.18 per 100,000 for age group 20 to 24 to a high of 5.5 per 100,000 for age group 40 to 44.

*Six-year average age-adjusted incidence rates with 1987 female population used as denominator.

In the various age groups the age-specific incidence rates for squamous cell carcinoma of the cervix generally are of the order of 2 to 6.5 times the incidence rates for adenocarcinoma.

The cumulative annual age-specific incidence rates of adenocarcinoma and squamous cell carcinoma of the cervix are given in Fig. 1, *A*. The cumulative rates increase with age for both histologic types. However, the observed ratio of the cumulative rates for squamous cell carcinoma to the cumulative rates for adenocarcinoma increases with age. For adenocarcinoma the cumulative age-specific incidence rates among both Hispanics and Asians and Pacific Islanders are higher in all age groups above 45 (Fig. 1, *B*). It also appears that Asians and Pacific Islanders have the highest cumulative incidence rates for adenocarcinoma at all age groups above 45. For squamous cell carcinoma, above the age of 45 both Hispanics and Asians and Pacific Islanders have cumulative age-specific rates that are consistently higher than the corresponding rates for non-Hispanic whites (Fig. 1, *C*). However, Hispanics appear to have the highest cumulative incidence for

squamous cell carcinoma, in contrast to adenocarcinoma, at all ages.

Stage at diagnosis and histologic type. The data on the distribution of cases by summary stage at diagnosis (localized, regional, and distant disease involvement) and histologic type are presented in Table III. For patients with squamous cell carcinoma, 45.7% had localized disease at diagnosis compared with 58.6% for patients with adenocarcinoma (Table III). At diagnosis 4.4% of patients with squamous cell carcinoma and

2.6% of patients with adenocarcinoma had unknown stage. The distribution of squamous cell carcinoma and adenocarcinoma by stage at diagnosis is significantly different ($p < 0.05$). When cases were classified further by age groups (Table IV), the distribution by stage at diagnosis differed significantly between squamous cell carcinoma and adenocarcinoma only for the age group 40 to 54 years; 70.0% of cases of adenocarcinoma were diagnosed at the localized stage, compared with 45.6% of cases of squamous cell carcinoma ($p = 0.05$) (Table IV). There were no significant differences in stage at diagnosis for the two cell types in the remaining age groups, <40 and ≥55. The distribution of cases by stage at diagnosis and histologic type is examined further by ethnicity in Table V. In each ethnic group the trend is toward less aggressive disease in adenocarcinoma than in squamous cell carcinoma, although the differences are not statistically significant.

Survival by histologic type. The survival in cases of adenocarcinoma and squamous cell carcinoma of the cervix is presented in Fig. 2, *A*. After adjustment for differences in age at diagnosis, the survival of the two groups defined by histologic type was not significantly different ($p = 0.76$). Fig. 2, *B* and *C*, presents the survival by stage at diagnosis for adenocarcinoma and squamous cell carcinoma of the cervix, respectively. For both cell types the survival differed significantly by stage at diagnosis ($p < 0.001$). After adjustment for both age and stage at diagnosis the survival of the two histologic groups was not significantly different ($p = 0.87$).

Comment

The population sample studied was 678 patients with invasive histologically confirmed cervical cancer, diagnosed during the 6-year period 1984 through 1989 and identified as a part of the population-based cancer registry, the Cancer Surveillance Program of Orange County. Of all cases studied, 457 (67.4%) were squamous cell carcinoma and 152 (22.4%) were adenocarcinoma. In this study differences between the two histologic types are shown with respect to age-adjusted incidence rates, age-specific rates, age-adjusted and age-specific rates classified by ethnic group, distribution by stage at diagnosis, and survival with adjustment for stage at diagnosis and age.

The proportion of adenocarcinoma found in this study (22.4%) is higher than that reported by previous investigators.[2-4, 6, 7, 9] Horowitz et al.[1] reported a study of 333 patients with cervical cancer diagnosed at Johns Hopkins, 16% of which cases were adenocarcinoma. These authors studied differences in demographic and

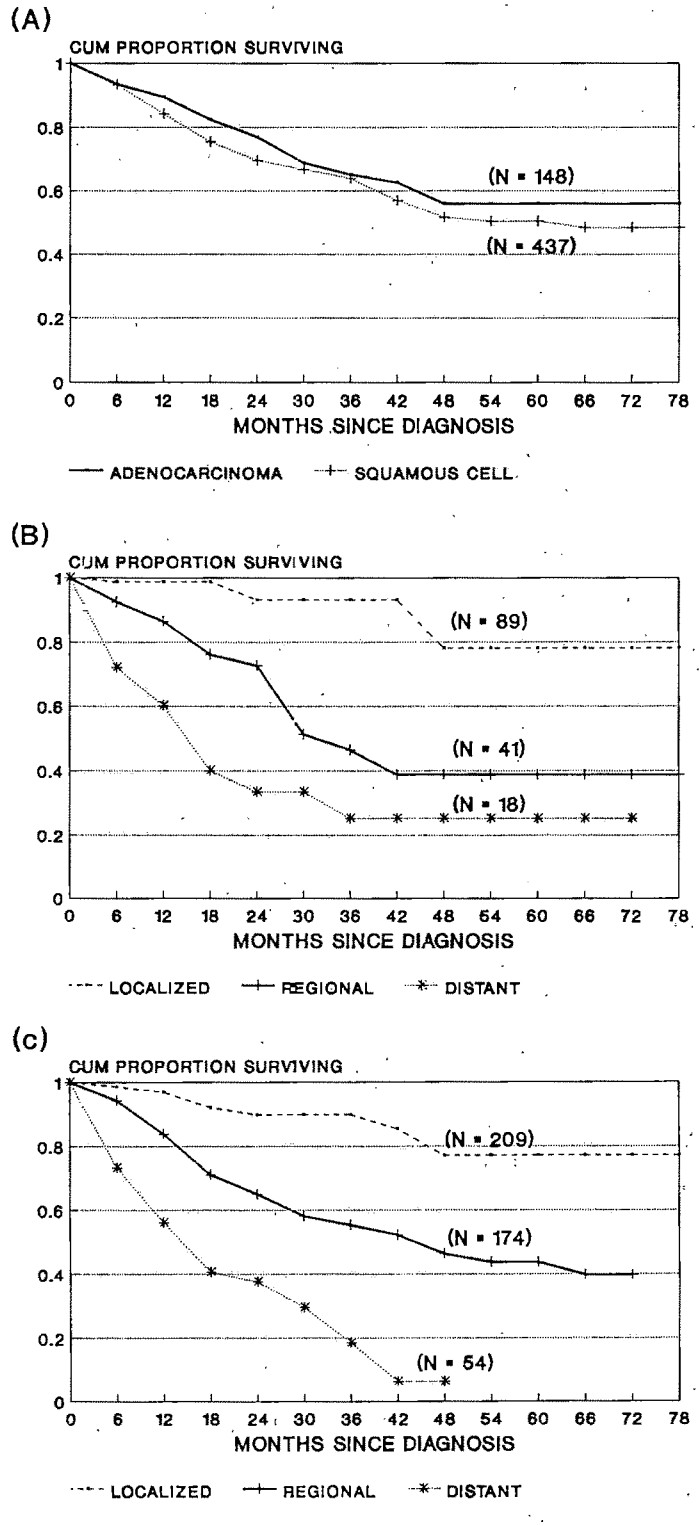

Fig. 2. Cumulative survival of patients with cervical cancer diagnosed in 1984 through 1989 by histologic type **(A)**, by stage at diagnosis for adenocarcinoma **(B)**, and by stage at diagnosis for squamous cell carcinoma **(C)**.

socioeconomic factors between the two histologic groups, concluding that their "data suggest that epidermoid and adenocarcinoma of the cervix may represent diseases with distinct populations at risk."[1] Silcocks et al.[3] report a study of squamous cell and adenocarcinoma of the cervix with data from the South Thames cancer registry, showing only 13.2% of all invasive carcinoma of the cervix to be of adenomatous histologic type. Several other reports suggest that the proportion of adenocarcinoma of the cervix is increas-

ing over time.[1, 2, 8, 9] The proportions reported in these studies range from 7% to 20%.

The difference in the proportion of adenocarcinoma reported in this study may well be a result of the variability in the ethnic distribution of the population at risk. None of the previously reported studies present data on incidence rate or distribution of histologic types by ethnic group; the data on the ethnic distribution of the population at risk in these studies were not reported. The data from the present study indicate differences among ethnic groups with regard to the risk for adenocarcinoma and squamous cell carcinoma and to differences in the stage at diagnosis.

Hispanics appear to be at highest risk for squamous cell carcinoma at all ages, followed by Asians and Pacific Islanders and then non-Hispanic whites. For adenocarcinoma Asians and Pacific Islanders have the highest age-adjusted incidence rates, followed by Hispanics and again non-Hispanic whites with the lowest rates (Table II). For the three ethnic groups combined, the risk for squamous cell carcinoma is highest (16.1/100,000) at age 65 to 69, whereas in adenocarcinoma the incidence rate is highest (5.5/100,000) for age group 40 to 44. Furthermore, 45.7% of squamous cell carcinomas are diagnosed at a localized stage, compared with 58.6% of adenocarcinomas. The distribution by stage of diagnosis of the two histologic types is significantly different ($p < 0.05$) (Tables III and IV).

The data from the current study, with respect to incidence rate, age at diagnosis, and stage of diagnosis for each of the three ethnic groups, indicate that adenocarcinoma is less aggressive than squamous cell carcinoma (Table V). In general, adenocarcinomas were diagnosed at an earlier stage than squamous cell carcinomas regardless of age and ethnicity. These differences are most pronounced in women aged 40 to 54 and in Hispanic women. This finding is directly opposite to the popular belief that adenocarcinomas are usually more advanced than squamous cell carcinomas at the time of diagnosis. A generally accepted rationale for this belief is that adenocarcinoma occurs high in the endocervical canal and is therefore hidden from early diagnosis by inspection or Papanicolaou smear.

Within each of the two groups defined by histologic type, survival is significantly different by stage at diagnosis. As expected, survival is inversely related to the advancement of the disease at diagnosis, which is in general agreement with earlier reports of survival.[2, 4, 6, 7, 17, 18] In this study survival did not differ by histologic type when adjusted for stage at diagnosis and age. This finding differs from conclusions of other investigators who have suggested that adenocarcinoma carries a worse prognosis.

In conclusion, we have compared the epidemiologic and clinical behavior of adenocarcinoma with that of squamous cell carcinoma of the uterine cervix with a population-based cohort. Major differences between the two histologic types were found in the age at diagnosis (adenocarcinoma earlier than squamous cell carcinoma), the extent of disease at diagnosis (adenocarcinoma less advanced than squamous cell carcinoma), and differences in the age-adjusted incidence rate with regard to ethnic distribution. In spite of these epidemiologic differences, prognosis and survival were not affected by histologic type.

We thank all staff of the Cancer Surveillance Program at Orange County whose contributions to the collection and processing of data make this publication possible, particularly Tom Kurosaki and Thomas H. Taylor, PhD. We also thank the Orange County Health Care Agency staff, the Orange County Administrative Office staff, the American Cancer Society, Orange County Unit, and Frieda van Schijndel for her assistance in the preparation of this manuscript.

A review of premature birth and subclinical infection

R.S. Gibbs, MD,[a] R. Romero, MD,[b] S.L. Hillier, PhD,[c] D.A. Eschenbach, MD,[c] and R.L. Sweet, MD[d]

Denver, Colorado, Detroit, Michigan, Seattle, Washington, and San Francisco, California

Premature birth causes high rates of neonatal morbidity and mortality. There are multiple causes of preterm birth. This article reviews the evidence linking subclinical infection and premature birth. Although maternal genital tract colonization with specific organisms has been inconsistently associated with preterm birth and/or premature rupture of membranes, some infections have been consistently associated with preterm delivery. The association of histologic chorioamnionitis with prematurity is a consistent finding, but the mechanisms require further study. The relationship between histologic chorioamnionitis infection and the chorioamnionitis of prematurity requires additional research. A varying number of patients in "idiopathic" preterm labor have positive amniotic fluid cultures (0% to 30%), but it is not clear whether infection preceded labor or occurred as a result of labor. Evidence of subclinical infection as a cause of preterm labor is raised by finding elevated maternal serum C-reactive protein and abnormal amniotic fluid organic acid levels in some patients in preterm labor. Biochemical mechanisms for preterm labor in the setting of infection are suggested by both in vitro and in vivo studies of prostaglandins and their metabolites, endotoxin and cytokines. Some, but by no means all, antibiotic trials conducted to date have reported decreases in prematurity. These results support the hypothesis that premature birth results in part from infection caused by genital tract bacteria. In the next few years, research efforts must be prioritized to determine the role of infection and the appropriate prevention of this cause of prematurity. (AM J OBSTET GYNECOL 1992;166:1515-28.)

Key words: Premature birth, subclinical infection, biochemical mechanisms, chorioamnionitis, antibiotics

Preterm birth is the leading perinatal problem in the United States. The underlying cause of preterm birth is not evident in most cases, and currently, physicians are left with marginally effective attempts to delay delivery by arresting contractions. Breakthroughs in the prevention of preterm birth will require an improved understanding of its causes followed by appropriate strategies to prevent these causes. Evidence from several sources suggests a link between subclinical infection and prematurity. In August 1990 a symposium, sponsored by the Infectious Disease Society of Obstetrics and Gynecology, was held to discuss this evidence. This article summarizes the presentations and includes additional data presented since the symposium.

Prematurity in perspective

The problems of being born premature or with low birth weight (LBW) are well documented. LBW leads to excessive neonatal mortality and morbidity. More than 60% of the mortality that occurs among infants without anatomic or chromosomal congenital defects is attributable to LBW.[1] A similar excess of morbidity also exists in the LBW group. The Surgeon General placed a high priority on the reduction of LBW by 1990. However, the rate of LBW has not appreciably changed in the United States over the past 40 years.[2] Approximately 6.7% of infants are born with LBW and 1% are born with very low birth weight (<1500 gm).[3] The United States ranks nineteenth in the world in infant mortality, behind virtually all European countries and in the same range as many third-world countries.

In contrast, the neonatal mortality rate has been dramatically reduced over the same 40 years in the United States,[4] caused mainly by improved care of LBW infants in neonatal intensive care units.[2] In fact, weight for

weight, an infant has the best survival rate in the United States. Thus, given a high LBW rate, infant mortality would be even higher in the United States were it not for high technology and expensive neonatal care. It is apparent that the emphasis of medical care for this problem in the United States has been placed on costly tertiary care rather than on prevention.

The main reason for a continued high LBW rate is a poor understanding of antenatal factors that contribute to an infant with LBW. One cannot expect to reduce LBW or even to appreciate the relative importance of various potential factors until the various causes are determined. Most investigators have assumed a final common pathway by which a variety of normal and pathologic processes eventually influence the human endocrinologic system that, in turn, causes uterine contractions and labor. While parts of this system have been identified in certain animals, processes important in human parturition are less clear. Without additional knowledge on the essential pathway, it has been difficult to identify the mechanisms by which various processes result in premature contractions or delivery.

To date, multiple factors have been associated with LBW. Determination of factors that are important causes of LBW awaits further study. Some factors appear highly associated with infant mortality and LBW because of consistent findings, a high relative risk ratio, or a high frequency of the factor in the population. Risk factors for both neonatal and postneonatal mortality include both low (<17 years) and high (>34 years) maternal age, black race, and low socioeconomic status.[2] These same three factors plus a history of an adverse pregnancy outcome, inadequate prenatal care, rupture of membranes, multiple pregnancies, medical conditions such as hypertension and diabetes, fetal anomalies, and drug abuse are some of the more important factors associated with LBW.[2] While some of these factors cause premature delivery, others such as socioeconomic status are only associated with preterm delivery.

Premature rupture of membranes is associated with about one third of LBW deliveries. Premature rupture of membranes has been reported to be the third leading cause of perinatal death in the collaborative perinatal project after "amniotic fluid infection" and abruptio placentae.[5] Factors associated with premature rupture of membranes include premature rupture of membranes in a prior pregnancy,[6] histologic chorioamnionitis,[7] abnormal bleeding, polyhydramnios, incompetent cervix, smoking,[8] and selected vaginal microorganisms[9] in the current pregnancy. Infection appears to be an important theme in premature rupture of membranes.

Recently, convincing evidence has associated LBW with infection. High rates of amniotic fluid infection, chorioamnion infection, and histologic chorioamnionitis have been reported in LBW pregnancies.[10] The highest proportion of these three infections occurs in the most premature pregnancies, an observation that adds to the impact of infection in LBW.

Prevention of LBW and premature rupture of membranes can be targeted (1) to prevent the initiation of labor or premature rupture of membranes or (2) to inhibit preterm labor after it is recognized. Programs for prevention of preterm labor have had only limited success. The targeted treatment of cervical or vaginal infection has led to only a modest reduction of preterm labor and premature rupture of membranes, and the overall impact on preterm labor may be limited. Treatment of premature labor with tocolysis also has had limited impact on LBW and premature rupture of membranes.

Experimental difficulties exist in establishing the role of infection in LBW and premature rupture of membranes. Many LBW deliveries occur without placental or amniotic fluid infection. Antibiotic treatment of uninfected pregnancies would have no effect and inclusion of uninfected pregnancies into such treatment studies will usually mask any positive antibiotic effect. The detection of infection requires sensitive techniques because most maternal infection is subclinical. Upper genital tract infection most directly influences preterm delivery and sampling of the upper genital tract is difficult, particularly before premature labor. Whereas amniotic fluid can be sampled before delivery, the majority of infections occur in the placenta and currently it is not possible to sample the placenta before delivery. A cause-and-effect relationship is even harder to establish after an event has transpired.

Specific microorganisms associated with preterm birth

The first evidence that suggested a connection between infection and premature birth occurred with an association of a variety of cervicovaginal microorganisms with preterm delivery, LBW, or premature rupture of membranes (Table I). The next question was whether those lower maternal genital tract isolates were related to upper genital tract infection and, further, whether the relationship between upper genital tract infection and preterm birth, LBW, and premature rupture of membranes was a cause or an effect.

Syphilis has been related to preterm birth for many years. Untreated primary or secondary syphilis resulted in a 50% rate of prematurity compared with an 8% rate among controls.[11] Early latent syphilis resulted in a 20% prematurity rate. The association of syphilis with premature delivery has been reconfirmed during the current epidemic of congenital syphilis in which mean gestational age for newborns with congenital syphilis was 32.3 weeks. Twelve (39%) of 33 infants with congenital

syphilis and none of the controls had premature rupture of membranes.[12]

Untreated *N. gonorrhoeae* has been associated with preterm delivery.[13-16, 16A] In addition, treatment of *N. gonorrhoeae* reduces rates of preterm delivery and low birth weight similar to that of control populations, suggesting a causative role of *N. gonorrhoeae* in these events.

Asymptomatic group B streptococci bacteriuria has been consistently associated with preterm delivery. Preterm delivery rates of 20% versus 8.5%[17] and 7.2% versus 4.9%[18] occurred among women with bacteriuria with and without group B streptococci, respectively. A sevenfold decrease in preterm delivery resulted when antibiotics were administered (5.4%), compared with placebo (37.5%).[19] The extraordinarily high rate of prematurity in the bacteriuric group suggests that additional risk factors for prematurity may have been present.

In comparison to the consistent association with bacteriuria, the relationship of maternal group B streptococci genital colonization and adverse pregnancy outcome has been inconsistent. Five of the six studies assessing genital tract group B streptococci colonization with preterm labor or delivery demonstrated no significant association.[20-25] However, a significant association was found in three of four studies assessing the relationship of genital group B streptococci colonization and in preterm premature rupture of membranes[21, 22, 26, 27] (Table II).

In case-control studies genital tract mycoplasmas, especially *U. urealyticum*, have been associated with LBW.[28, 29] A subgroup of pregnant women with serologic evidence of invasive *U. urealyticum* infection (more than a fourfold rise in antibody) has been associated with LBW.[30] The mean birth weight was 233 gm lower in the group with an antibody response (3006 ± 565 vs 3229 ± 474 gm, $p = 0.009$). The clinical significance of a 200 gm difference at a 3 kg birth weight is questionable. A larger proportion of newborns weighing <2500 gm were born to mothers with a fourfold rise in antibody to *U. urealyticum* (38%, 10/27) compared with infants weighing >2500 gm (15%, 33/219). However, recent studies have failed to confirm such an association. None of the 11 cohort studies performed[31-41] support an association between *U. urealyticum* and prematurity or LBW. The treatment of *U. urealyticum* with erythromycin had no impact on LBW or premature rupture of membranes.[42] *M. hominis* has been inconsistently related with LBW; the relationship has been positive in some[25, 26, 31, 38, 42A] but not other[28, 35, 38] studies. Thus the majority of investigations have failed to provide evidence supporting an association between colonization of the maternal genital tract with *U. urealyticum* and preterm delivery or LBW. Data regarding *M. hominis* are less clear in relating this organism to prematurity.

Table I. Microorganisms or infections associated with preterm labor, preterm delivery, and preterm premature rupture of the membranes

Organisms
Treponema pallidum
Neisseria gonorrhoeae
Group B streptococci
Ureaplasma urealyticum
Mycoplasma hominis
Chlamydia trachomatis
Trichomonas vaginalis
Bacteroides sp.
Infections
Bacterial vaginosis
Pyelonephritis
Bacteriuria

The presence of *C. trachomatis* in the cervix at the initial prenatal visit was associated with spontaneous abortion, stillbirth, preterm delivery, and LBW.[38] The mean gestational age was 35.9 weeks in those with and 39.2 weeks in those without *C. trachomatis* ($p < 0.01$).[38] LBW was also associated with *C. trachomatis* in this study. Subsequent studies by Thompson et al.,[39] Harrison et al.,[31] and Hardy et al.[40] failed to confirm an overall association between chlamydia infection and adverse pregnancy outcome. However, Harrison et al. reported that a subgroup of women with cervical *C. trachomatis* and elevated levels of IgM antibody against *C. trachomatis* (suggestive of recent acquistion or active infection) had a significantly increased risk of premature rupture of membranes, LBW, and preterm delivery.[31] Sweet et al.[35] confirmed these findings. After controlling for the presence of other sexually transmitted disease organisms in a multivariate analysis, the association was no longer significant.[35] In another investigation *C. trachomatis* remained associated with LBW and premature rupture of membranes in a multivariate analysis controlling for bacterial vaginosis and obstetric factors related to prematurity.[43] Several other recent investigations support an association of *C. trachomatis* with preterm delivery.[25, 26, 37, 42A] Thus further large-scale studies that also use serologic assessment will be required to resolve the controversy over the role of *C. trachomatis* in preterm delivery and premature rupture of membranes.

The association of *T. vaginalis* with preterm delivery has also been a source of controversy. *T. vaginalis* was not associated with LBW,[44] and treatment was not associated with an increase in birth weight or gestational age in a placebo-controlled trial.[45] However, among adolescents, the incidence of LBW was 18% in patients with versus 6.7% in those without *T. vaginalis*

($p = 0.06$).[40] Further, in the large Vaginal Infections and Prematurity Study, *T. vaginalis* carriage at midpregnancy was significantly associated with LBW and premature rupture of membranes after adjustment for confounding factors and other microorganisms (Cotch MF. Personal communication, ICAAC abstracts, 1990). Finally, the incidence of premature rupture of membranes at term was 27.5% in women with positive cultures compared with 12.8% in those with negative cultures for *T. vaginalis* ($p < 0.03$).[22]

Bacteroides sp. have also been implicated in preterm delivery and/or premature rupture of membranes. In a stepwise logistic regression analysis, women colonized with *Bacteroides sp.* at their initial prenatal visit had a 40% increased preterm delivery rate compared with that for noncolonized women ($p = 0.003$).[22] Nonfragilis *Bacteroides sp.* were more often recovered from the cervices of women in spontaneous preterm labor (21% of 72) compared with those women not in labor but at a similar gestational age (4% of 26, $p = 0.03$).[25] Black-pigmented *Bacteroides sp.* were more frequently recovered from women in preterm labor who were delivered at <37 weeks (20% of 61) compared with control women at term (8% of 155, $p < 0.05$).[26] More recently, vaginal *Bacteroides sp.* has been associated with a 60% increased risk of preterm delivery, and *Bacteroides bivius* $>10^4$ colony-forming units per milliliter was associated with a twofold increased risk of delivery at ≤34 weeks' gestation.[46, 47]

Bacterial vaginosis is a clinical condition in which the normal vaginal flora, characterized by high concentrations of lactobacilli, is replaced by high concentrations of anaerobic bacteria, especially *Bacteroides sp.* and *Mobiluncus sp.*, *Gardnerella vaginalis*, and *M. hominis*.[48] Several studies have suggested that bacterial vaginosis is associated with LBW and premature rupture of membranes.[10, 26, 43, 49] Premature rupture of membranes occurred significantly more commonly in the bacterial vaginosis group (46%) than in those without bacterial vaginosis (4%).[49] In a cohort of pregnant women, bacterial vaginosis in the second or third trimesters of pregnancy was associated with LBW and premature rupture of membranes by univariate analysis. Bacterial vaginosis remained significantly associated with preterm labor (odds ratio 2.0, $p < 0.05$) and preterm premature rupture of membranes (odds ratio 3.0, $p = 0.03$) in a multivariate analysis controlling for *C. trachomatis* and risk factors for premature delivery. No significant association was present between bacterial vaginosis and LBW in the multivariate analyses. In other studies, bacterial vaginosis with preterm labor[43] or preterm delivery[26] with an odds ratio of 2 to 3. In the only cohort study in which patients were enrolled early in pregnancy (first prenatal visit), bacterial vaginosis was associated with a trend for an association with preterm labor (50% vs 29%), but these results were not statistically significant.[22]

Untreated acute pyelonephritis is consistently associated with approximately a 30% risk of preterm labor and delivery. Asymptomatic bacteriuria (other than with group B streptococci) has been less consistently associated with an increased risk of LBW.[50-67] Only five of the 17 cohort studies that assessed birth weight reported a significantly increased incidence of prematurity (LBW) in women with asymptomatic bacteriuria.[51, 53, 54, 61, 63] However, in a meta-analysis in which weighting of studies was performed, women with asymptomatic bacteriuria had a 60% higher rate of LBW than nonbacteriuric women (95% confidence interval 1.4 to 1.9).[68] Similarly disagreement exists among the four cohort studies that assessed gestational age as a complication of asymptomatic bacteriuria.[52, 59-61] Two studies demonstrated a significantly increased preterm delivery rate in patients with asymptomatic bacteriuria,[59, 60] while two others did not.[52, 61] In a meta-analysis of all four studies, women with asymptomatic bacteriuria had a 90% higher preterm delivery rate than nonbacteriuric women (95% confidence interval 1.3 to 2.9).[68]

A large number of studies have addressed the issue

of whether maternal genital tract colonization is associated with preterm labor, preterm delivery, or premature rupture of membranes. The results are often conflicting. *N. gonorrhoea* and pyelonephritis have been highly related to preterm birth but their occurrence is infrequent. *U. urealyticum* in the genital tract is not associated with premature delivery. For the remaining lower genital tract microorganisms mentioned and for asymptomatic bacteriuria, the association with prematurity, where found, is low (relative risk 1.4 to 2) and perhaps confined only to subsets. For all of these microorganisms, a more convincing cause-and-effect relationship would exist if the microorganism could be isolated from the amniotic fluid or placenta if women who are delivered of LBW infants have premature rupture of membranes.

Histologic chorioamnionitis and prematurity

Histologic chorioamnionitis, defined as inflammation of the extraplacental membrane, has been consistently linked with prematurity, LBW, and premature rupture of membranes. Histologic chorioamnionitis is detected in 19% to 74% of placentas from preterm deliveries and in 4% to 16% of placentas from term deliveries.[10, 69-71] Although mothers with histologic chorioamnionitis usually have no clinical evidence of infection, their infants have increased rates of sepsis and death.[70] The role of infection in the etiology of histologic chorioamnionitis has been investigated in several recent studies. In both preterm and term placentas, microorganisms have been recovered in 51% to 71% of placentas with 23% to 45% of those without histologic chorioamnionitis (Table III).[10, 72-75] The relationship between histologic chorioamnionitis and infection (positive cultures) of the chorioamnion is strongest among preterm deliveries[10] while it is less strong in term placentas.[76]

In spite of the strong statistical associations between chorioamnionitis and placental membrane infection, 18% to 49% of placentas with histologic evidence of chorioamnionitis are culture negative. This may reflect lack of culture sensitivity or a nonmicrobial cause of inflammation. From 15% to 45% of infected membranes are free of inflammation (Table III). Chorioamnion infection without inflammation may be related either to infection that starts at or near the time of delivery (before an inflammatory response is produced) or to contamination by vaginal bacteria. The infrequency of lactobacilli (a common vaginal contaminant) in placental cultures argues against frequent contamination (Table IV).

Microorganisms most commonly isolated from the chorioamnion include *U. urealyticum*, facultative and anaerobic gram-positive cocci, *G. vaginalis*, and *Bacteroides sp.* (Table IV). Surprisingly, coliforms are uncommon isolates. Likewise, *Haemophilus influenzae* and *N. gonorrhoeae* are rarely recovered from the chorioamnion even though these organisms can cause chorioamnionitis when they are present.[77, 78] In spite of widespread attempts, *C. trachomatis* is rarely recovered from the placenta. Fastidious anaerobes including *Mobiluncus* and *Fusobacterium sp.* may be underrepresented in current studies because of difficulties in isolating these organisms. Thus species of the vagina are found among microorganisms causing placental infection, but many such species appear to have tropism for the placenta.

While the association of histologic chorioamnionitis and prematurity has been well described, the effects of chorioamnion infection on the neonate are less understood. Histologic chorioamnionitis has been associated with an increased perinatal death rate, and infants born to women with chorioamnionitis have had a high prevalence of elevated antibody to *U. urealyticum*.[74] The effects of chorioamnion infection on neonatal outcome require further study to determine which placental pathogens present the greatest risk for poor neonatal outcome.

How does chorioamnion infection lead to premature rupture of membranes and/or preterm delivery? Schoonmaker et al.[79] have demonstrated that group B streptococci significantly decreased placental membrane integrity (i.e., lower bursting tension, less work to rupture, and less elasticity) in vitro, suggesting that placental infection could predispose to membrane rupture. Bernal et al.[80] have demonstrated that the fetal membranes from women with chorioamnionitis produce significantly higher levels of prostaglandin E_2 in vitro. It is likely that production of prostaglandin E_2 is

significantly higher in women with chorioamnion infection. Lamont et al.[81] have demonstrated the *Bacteroides*-conditioned media–stimulated production of prostaglandin E_2 by human amnion cells in vitro. These authors suggested that bacterial phospholipase releases arachidonic acid from the amnion, leading to prostaglandin E_2 synthesis. Whereas further studies of how chorioamnion infection may cause preterm delivery are needed, the published data suggest that chorioamnion infection is strongly related to inflammation and weakening of the placental membrane and to stimulation of prostaglandin production by the amnion.

Amniotic fluid culture in premature labor

Further evidence to link prematurity with infection comes from amniotic fluid cultures of patients with intact membranes in preterm labor. In view of differences in sample size, in definition of preterm labor, and in microbiologic techniques, it is not surprising that the percent of patients with positive cultures varied widely from 0% to 30%[82-91] (Table V). In a recent large series positive cultures were present in 11% of 264 women in preterm labor but in 22% of 111 women who were delivered within 24 to 48 hours of admission.[87] Patients in premature labor and with a positive amniotic fluid culture are usually delivered within 24 to 48 hours in contrast to culture-negative patients who tend to be delivered >30 days later.[87, 89]

These data provide strong circumstantial, but not strong causal, evidence that infection causes the preterm delivery. Difficulties in demonstrating a cause-and-effect relationship would require providing evidence (1) that infection preceded labor rather than vice versa, (2) that cultures are less frequently positive in comparable patients in term labor, and (3) that antibiotic therapy of those infected reduces preterm delivery.

Indirect "markers of infection" in premature labor

Amniotic fluid cultures may be an insensitive test to detect infection that begins in the decidua or amnion. In fact, a high rate of positive chorioamnion cultures occurs in preterm births.[10] Other "markers" of infection that have been assessed in patients in preterm labor include elevated C-reactive protein levels in maternal sera and short-chain organic acids (produced by bacterial metabolism) in amniotic fluid, detected by gas-liquid chromatography. Elevated serum C-reactive protein levels are part of the acute-phase reaction. Most women (86% to 88%) in preterm labor and with high C-reactive protein values do not respond to tocolytics.[92-94] In contrast, most patients with a normal C-reactive protein level responded to tocolytics (77% to 94%).[92-94]

Detection of abnormal organic acids in amniotic fluid was reported in all of six women in preterm labor, but in comparison none of five normal women not in labor had abnormal amniotic fluid acid levels. Only one had a positive culture. The authors suggested that the origin of these abnormal organic acids is bacterial growth in the uterine cavity.[95] The report of Wager et al.[96] did not confirm the value of the gas-liquid chromatography in this setting.

Other biochemical markers are discussed in the next section.

Biochemical mechanisms linking prematurity and infection

Prostaglandins. Until recently, prostaglandins have been considered the universal mediators of parturition in mammalian species.[97-101] Traditional evidence that supports the participation of prostaglandins in the mechanism of labor in humans includes the following: (1) Administration of prostaglandins results in abortion

or labor; (2) treatment with prostaglandins inhibitors delays the process of midtrimester abortion and the onset of labor and can arrest preterm labor; (3) parturition at term is associated with elevated amniotic fluid and maternal plasma concentrations of prostaglandins; (4) arachidonic acid (prostaglandin precursor) concentrations in the amniotic fluid increase during labor; (5) intraamniotic administration of arachidonic acid results in labor.

The evidence supporting a role for prostaglandins in the mechanisms responsible for preterm labor is less firm than for term labor.[101-111] In both plasma and amniotic fluid, levels of prostaglandins have been either normal[100-102] or increased[103, 104] in women in preterm labor. The discrepancies between these studies may be attributed to the heterogeneous nature of diseases causing preterm labor. Patients with preterm labor and microbial invasion of the amniotic cavity have significantly higher amniotic fluid concentrations of prostglandin E_2 and $F_{2\alpha}$ and their stable metabolites (bicycloprostaglandin E_2 and 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$) than women in preterm labor with negative amniotic fluid cultures.[105-111] In contrast, amniotic fluid concentrations of prostaglandins E and $F_{2\alpha}$ are not different between women in preterm labor with negative amniotic fluid cultures and women without labor with negative cultures at similar gestational ages.[108] These findings are consistent with the observation that the production of prostaglandins by amnion and chorion-decidua is higher in patients with preterm labor and histologic chorioamnionitis than in patients with no evidence of placental inflammation. These data suggest an increased bioavailability of prostaglandins in preterm parturition associated with infection. It remains to be proved whether prostaglandins play a role in preterm labor not associated with infection.

Arachidonate lipoxygenase metabolites. Metabolites of arachidonic acid derived through the lipoxygenase pathway involving leukotrienes and hydroxyeicosatetraenoic acids have also been implicated in the mechanisms of spontaneous parturition at term.[112-117] Arachidonate lipoxygenase products are inflammatory mediators, so it is possible that they also participate in the mechanisms of preterm labor associated with infection. Concentrations of 5-hydroxyeicosatetraenoic acid, leukotriene B_4, and 15-hydroxyeicosatetraenoic acid are increased in the amniotic fluid of women with preterm labor and with microbial invasion of the amniotic cavity.[118-120] Similarly, amnion from patients with histologic chorioamnionitis releases more leukotriene B_4 in vitro than amnion from women delivered preterm without inflammation.[121]

The precise role of arachidonate lipoxygenase products in parturition in association with infection remain to be determined. 5-Hydroxyeicosatetraenoic acid and leukotriene C_4 may stimulate uterine contractility, and leukotriene B_4 may recruit neutrophils to the site of infection and participate in the regulation of the cyclooxygenase pathway.[122, 123] Leukotriene B_4 has been shown to act as a calcium ionophore[124] and thus may increase phospholipase activity and enhance the rate of prostaglandin synthesis by intrauterine tissues.

Bacterial products. For the past decade the explanation of the onset of labor in the setting of infection has been that bacterial products directly stimulate prostaglandin biosynthesis[125, 126] and bacterially conditioned media stimulate prostaglandin production by human amnion.[127-129] Although the specific product(s) responsible for this effect has not been established, one candidate is endotoxin (lipopolysaccharide). Lipopolysaccharide is a component of the wall of gram-negative bacteria, and it can stimulate prostaglandin production by macrophages, amnion,[130] and decidua.[131] Lipopolysaccharide has been found in the amniotic fluid of women with intraamniotic infections,[132, 133] and in cases of preterm premature rupture of membranes, amniotic fluid concentrations of endotoxin are higher in patients in labor than in patients not in labor.[134] Other bacterial products that may stimulate prostaglandin production are peptidoglycans in cases with gram-positive bacterial infection.

However, bacterial products alone may not be responsible for the onset of preterm labor in the setting of infection. One third of women with preterm premature rupture of membranes without labor have organsims in the amniotic cavity, suggesting that the presence of microorganisms in the amniotic cavity per se is not sufficient to produce labor. Further, the effects of microbial products on prostaglandin production by intrauterine tissues are highly dose dependent and may even be inhibitory.[135] The quantitative aspects of these biologic effects appear important. For example, the concentrations of lipopolysaccharide required to elicit prostaglandin production by amnion cells are rarely present in the amniotic cavity.[134]

Cytokines. The traditional view has been that through the release of toxins or enzymes the microorganisms were directly responsible for the metabolic

derangements associated with infection. It has now been established that endogenous host products secreted in response to infection are responsible for many of the effects of infection. In endotoxin shock, for example, bacterial endotoxins exert their deleterious effect through the release of endogenous mediators such as tumor necrosis factor and interleukin-1.

Parturition in the setting of infection may be signaled by secretory products of macrophage activation (monokines), including interleukin-1, tumor necrosis factor, and interleukin-6. The first monokine implicated in the onset of labor in the setting of infection was interleukin-1: (1) Interleukin-1 stimulates prostaglandin production by amnion and decidua in vitro[136]; (2) human decidua can produce interleukin-1 in vitro in response to bacterial products[137, 138]; (3) amniotic fluid interleukin-1 bioactivity and concentrations are elevated in patients with preterm labor and bacteria in the amniotic cavity,[139] but interleukin-1 is not present in fluid from patients with preterm labor and no bacteria; (4) among patients with preterm premature rupture of membranes and bacteria in the amniotic cavity, amniotic fluid interleukin-1 bioactivity and concentrations are higher in patients with than in those without labor,[139] indicating it is not the presence of microorganisms per se but rather the host response that is associated with parturition; (5) in vitro perfusion of human uteri with interleukin-1 elicits uterine contractility (unpublished data); (6) administration of interleukin-1 to pregnant animals leads to abortion and preterm labor (Romero R, Mazor M, Tartakovsky B. Unpublished observations).

Tumor necrosis factor, a cytokine released during macrophage activation, is also capable of stimulating prostaglandin production by several cell types. Evidence supporting a role of tumor necrosis factor in human parturition in the setting of infection includes: (1) Tumor necrosis factor stimulates prostaglandin production in vitro by human amnion and decidua[131, 140]; (2) tumor necrosis factor is produced by human decidua in response to bacterial products[141, 142]; (3) tumor necrosis factor is absent in normal amniotic fluid but present in the amniotic fluid of patients with intraamniotic infection and preterm labor[140]; (4) tumor necrosis factor can induce premature labor when administered to pregnant mice (Romero R. Unpublished observations).

Interleukin-6 is also a major mediator of the host response to infection. Interleukin-6 is produced by a variety of cells including macrophages and endometrial stromal cells. Major change in the biochemical, physiologic, and immunologic status of the host occurs from interleukin-6, including an acute-phase plasma protein response and the induction of other cytokines such as interleukin-1 and tumor necrosis factor. Women in preterm labor with intraamniotic infection had higher amniotic fluid levels of interleukin-6 than women in preterm labor without intraamniotic infection.[143, 144]

Macrophage colony-stimulating factor is a cytokine that is capable of regulating the number of macrophages and their level of activation. Macrophage-colony stimulating factor is produced by human decidual explants in response to lipopolysaccharide and it is present in the amniotic fluid of women in preterm labor with intraamniotic infection.

Noncytokine bioactive agents secreted during the inflammatory process may also participate in this process. Platelet-activating factor is a lipid that is present in the amniotic fluid of women with preterm labor. This compound is capable of stimulating prostaglandin E_2 production by amnion and of directly stimulating myometrial contractions.

This evidence suggests that the host products of macrophage activation (cytokines) play a role in the mechanism of human parturition in the setting of infection. Systemic maternal infections, such as pyelonephritis, or localized infections, such as deciduitis, could signal parturition through monocyte-macrophage activation in peripheral blood and decidua. Preterm labor can be viewed as an event occurring when the intrauterine or maternal environment is hostile and threatens the well-being of the fetus. The initiation of preterm labor in the setting of infection may be considered to have survival value.

Antibiotic trials to prevent premature birth

With the evidence that subclinical infection is a major cause of preterm birth, the logical extension is to conduct antibiotic intervention trials in an attempt to prevent prematurity. Trials to date have generally been of three designs: (1) antibiotic trials conducted antepartum in patients at high risk for preterm delivery; (2) antibiotic trials among women with premature labor but with intact membranes, as adjuncts to standard tocolytic therapy; and (3) antibiotic trials among women with preterm premature rupture of membranes but without preterm labor.

In the first antepartum antibiotic trial, patients with genital mycoplasmas in the lower genital tract were enrolled in a trial of erythromycin versus placebo for 6 weeks.[30, 145] Women in the erythromycin group, as compared with the placebo group, had a significantly higher mean birth weight (3331 vs 3187 gm, $p = 0.04$) and a lower rate of LBW (3% vs 12%, $p = 0.06$). In a study sponsored by the National Institutes of Health conducted at five centers, >900 patients with lower genital tract *U. urealyticum* were randomized to either erythromycin or placebo from the twenty-eighth through the thirty-fifth week of gestation.[42] Patients in the erythromycin group, compared with the placebo group, ex-

Table VI. Summary of antibiotic trials to delay delivery in preterm labor

Series and year	*No.*	*Regimen*	*Significant results in antibiotic group*			
			Delay in delivery	*Increase in birth weight*	*Increase in term delivery*	*Decrease in perinatal mortality*
McGregor et al.,[149] 1986	17	Erythromycin orally for 7 days	Yes	$p = 0.07$	No	No
Newton et al.,[150] 1989	95	Ampicillin intravenously for 2 days plus erythromycin for 4 days	No	No	No	No
Morales et al.,[151] 1988	150	Ampicillin orally or erythromycin orally, either for 10 days	Yes	No	Yes*	No
Winkler et al.,[152] 1988	19	Erythromycin orally for 7 days	Yes	No	Not reported	No

*For ampicillin versus placebo.

perienced no improvement in any of the following measures: rate of LBW, premature labor, preterm delivery, or preterm premature rupture of membranes. In the third study 229 patients at high risk for preterm delivery were randomized to a 7-day course of erythromycin or placebo.[146] No significant differences were present between the erythromycin and the placebo groups in preterm birth (7% vs 8%), mean birth weight (3132 ± 588 vs 3099 ± 548 gm), or preterm premature rupture of membranes (1.7% vs 4.6%). A significant reduction was observed in premature rupture of membranes at term between the groups (6% vs 16%, $p = 0.01$).

In two studies patients with cervical *C. trachomatis* were assessed for the effect of antibiotic treatment of pregnancy outcome. Patients successfully treated for *C. trachomatis* ($n = 244$) had significantly lower rates of premature rupture of membranes, premature labor, and small-for-gestational-age infants when compared with those who failed to respond ($n = 79$).[147] In a second report pregnancy outcome was studied in *C. trachomatis*–positive untreated patients ($n = 1110$), *C. trachomatis*–positive treated patients ($n = 1327$), and *C. trachomatis*–negative women ($n = 9111$). The untreated *C. trachomatis*–positive group had significantly increased rates of premature rupture of membranes and LBW and lower survival rates compared with those of both the treated *C. trachomatis*–positive group and those with negative cultures.[148] However, retrospective nonrandomized studies such as these are less convincing because of possible confounding factors.

In the first trial of the adjunctive use of antibiotics in patients in premature labor with intact membranes, a subgroup of patients with cervical dilatation between 1 and 5 cm who received adjunctive erythyromycin, as compared with the placebo group had significant prolongation of pregnancy (32 ± 11 vs 22 ± 7 days, $p = 0.02$), a significant improvement in patients delivered at term (87% vs 33%, $p = 0.04$), and an improvement in birth weight (2943 ± 483 vs 2615 ± 459 gm, $p = 0.07$).[149] Three additional studies of similar design have been reported.[150-152] In patients in preterm labor who received either ampicillin plus erythromycin for 4 days or placebo, there was no decrease in preterm birth (38% in the antibiotic group vs 44% in the placebo group).[150] In patients in idiopathic preterm labor randomized to one of the following regimens: ampicillin orally for 10 days, erythromycin orally for 10 days, or no antibiotic,[151] those receiving either ampicillin or erythromycin had significant prolongation of the pregnancy (31.7 days for ampicillin vs 28.5 days for erythromycin and 16.6 days for controls, $p < 0.05$) and patients receiving ampicillin compared with those receiving placebo also had a significantly higher rate of term delivery (45% vs 15%, $p < 0.05$). Among patients in idiopathic preterm labor randomized to either erythromycin for 7 days or placebo, a significant prolongation of the pregnancy occurred in the erythromycin group versus the placebo group (43 ± 25 vs 10 ± 19 days, $p < 0.05$).[152] Although there may be several reasons to explain the inconsistency of antibiotics in delaying delivery, there appear to be differences regarding the investigators' "intent to treat." For example, in the only "negative study" a high percentage of enrolled women were analyzed[150] whereas in the "positive studies" the percentage of enrolled patients ultimately analyzed was small.[149, 151] Even when antibiotic treatment has led to a prolongation of pregnancy, its use has not been accompanied by a consistent increase in birth weight and has not led to a decrease in perinatal mortality (Table VI).

Several recent randomized antibiotic trials have been conducted among patients with preterm premature rupture of membranes (Table VII). The hypothesis of these studies was that subclinical infection either causes premature rupture of membranes as a primary event

Table VII. Summary of antibiotic trials to delay delivery after preterm premature rupture of membranes

Series and year	No.	Regimen	Significant results in antibiotic group			
			Delay in delivery	*Increase in birth weight*	*Increase in term delivery*	*Decrease in perinatal mortality*
Amon et al.,[153] 1988	83	Ampicillin intravenously, then orally until delivery	Yes	No	No	No
Morales et al.,[154] 1989	82	Ampicillin intravenously "pending cultures"	Yes	No	No	No
Johnston et al.,[155] 1990	85	Mezlocillin intravenously, ampicillin orally until delivery	Yes	Yes	Yes	No
Christmas et al.,[156] 1990	56	Ampicillin gentamicin, clindamyin intravenously for 1 day, amoxicillin and clavulanic acid for 7 days	Yes	No	No	No

or causes the premature labor that ensues after preterm premature rupture of membranes. A significant increase was observed in pregnancies delivered >1 week after premature rupture of membranes in the ampicillin group versus the no-ampicillin group (47% vs 26%, $p = 0.05$).[153] This prolongation of pregnancy was not accompanied by a significant difference between groups in birth weight, gestational age at delivery, or hospital stay >30 days. In another report patients with preterm premature rupture of membranes were given betamethasone and randomized to ampicillin or no ampicillin.[154] No significant difference was found between those who had and those who had not received ampicillin in birth weight or in survival (93% vs 89%). Patients receiving ampicillin compared with those not receiving ampicillin had significantly less clinical amnionitis (4% vs 26%, $p < 0.01$). In the third study neither corticosteroids nor tocolytics were given to patients with preterm premature rupture of membranes.[155] Patients randomized to antibiotics versus placebo had a significant prolongation of pregnancy ≥7 days (45% vs 18%, $p < 0.01$), a significant increase in birth weight (1897 ± 600 vs 1587 ± 592 gm, $p < 0.05$), and a decrease in neonatal hospital stay >30 days (18% vs 38, $p < 0.05$). No significant differences were reported in perinatal mortality. In a smaller study antibiotic therapy compared with expectant management of patients with preterm premature rupture of membranes was associated with prolongation of pregnancy ≥8 days (36% of antibiotic groups vs 10% of expectant group, $p < 0.05$) but with no significant difference in mean birth weight, perinatal mortality, or respiratory distress syndrome.[156] These authors concluded that intervention with antibiotics delayed labor but offered no appreciable perinatal advantage.

In addition to these randomized trials there have been several interesting, innovative reports regarding the use of antibiotics in premature rupture of membranes. Successful eradication of "bacterial colonization" of the amniotic fluid was achieved by parenteral maternal antibiotic therapy in a preterm gestation with premature rupture of the membranes at 29 weeks' gestation.[57] Transcervical infusion of antibiotics into the amniotic cavity has occurred in patients with preterm premature rupture of membranes.[158, 159] Substantial antibiotic concentrations were achieved in the amniotic fluid, but the safety and efficacy of this approach have not been established.

In conclusion, current antibiotic trials allow no definite conclusion as the efficacy of antibiotics in prolonging pregnancy in patients with either preterm labor or preterm premature rupture of membranes. These discordant results may result from population differences. Antibiotics would be expected to have no effect, for example, among the subset of women with preterm labor–premature rupture of membranes if the cause is not infection. Differences in analysis of eligible patients also may have been important. For example, a positive study might be more likely if the investigators limited analysis to patients who completed versus those who did not complete the antibiotic course. Additional trials seem appropriate in view of results to date. However, randomized trials need to be conducted in selected groups at high risk for preterm delivery and/or infection or preferably in groups with specific infections or with evidence of preexisting infection such as histologic chorioamnionitis.

In the rhesus monkey placental retention after fetectomy at 121 to 130 days' gestation outlasts the normal duration of pregnancy

P.W. Nathanielsz, MD, PhD, J.P. Figueroa, MD, PhD, and M.B.O.M. Honnebier, MD
Ithaca, New York

OBJECTIVE: Our aim was to reassess the role of the fetus in the initiation of parturition in nonhuman primates. We tested the effect of the removal of the fetus at 121 to 130 days' gestation on the duration of gestation in pregnant rhesus monkeys.
STUDY DESIGN: Nine monkeys underwent fetectomy with the placenta in situ. Five monkeys underwent surgery without removal of the fetus.
RESULTS: In five control monkeys spontaneous vaginal delivery of live fetuses occurred at 163.8 ± 4.6 days' gestation (mean ± SD). In four of nine monkeys that underwent fetectomy the placenta delivered spontaneously at 185, 193, 201, and 207 days' gestation. The five remaining monkeys underwent cesarean section at 162, 189, 201, 202, and 219 days' gestation. Duration of placental retention in monkeys that underwent fetectomy (195 ± 16.1 days' gestation) exceeded that in controls ($p < 0.05$). Plasma progesterone and estradiol concentrations were normal for gestational age at fetectomy, indicating continued placental function.
CONCLUSION: We conclude that the presence of a live fetus plays a significant role in the determination of the duration of normal pregnancy in the rhesus monkey. (Am J Obstet Gynecol 1992;166:1529-35.)

Key words: Parturition, fetectomy, estradiol, progesterone, placenta, gestation length

The fetus plays a major role in the determination of the duration of gestation in the sheep. In this species decreased function of the fetal hypothalamopituitary-adrenal axis after placement of bilateral fetal paraventricular lesions,[1] fetal pituitary stalk section, fetal hypophysectomy, and bilateral fetal adrenalectomy[2] results in the prolongation of gestation. Conversely, infusions of either adrenocorticotropic hormone[2] or physiologic doses of cortisol[3] intravascularly to the fetal sheep will initiate parturition prematurely. It is unclear whether the primate fetus actively participates in the initiation of parturition. Controversy persists partly on the basis of results obtained in two studies that used different experimental approaches. First, large doses of glucocorticoids administered to the pregnant rhesus monkey will prolong gestation.[4] Second, in one often-quoted study removal of the fetus from 11 pregnant monkeys at a wide range of gestational ages (70 to 157 days' gestation) resulted in delivery of the placenta between 114 and 184 days' gestation. These authors stated, "The onset of labor is shown to be unquestionably independent of the immediate presence of the fetus."[5]

Somewhat different results were obtained by Lanman et al.,[6] who performed fetectomy in 13 pregnant rhesus monkeys. In this study the fetuses were also removed over a wide period, between 60 and 140 days' gestation. Estradiol or dexamethasone was administered to five of the 13 monkeys in connection with other studies. No contemporaneous control animals were used in either the study of Lanman et al. or the study by van Wagenen and Newton.[5] Lanman et al.[6] stated that in five of the eight animals that underwent fetectomy but received no other treatment the placenta was delivered outside the normal gestational age limits. Two of these five animals were only 4 days outside the given limits when the placenta was delivered.

To evaluate the role of the nonhuman primate fetus in determining the duration of gestation, instrumentation and fetectomy were performed in nine pregnant rhesus monkeys and five control pregnant monkeys underwent instrumentation in a similar way without fetectomy. Our major goal was to obtain data that would allow firm statistical comparison between the duration of placental retention after fetectomy and the duration of pregnancy in contemporaneous sham-operated controls. We also wished to evaluate the maintenance of plasma progesterone and estradiol concentrations after fetectomy. In addition, we wished to compare the pat-

terns of myometrial activity observed in pregnant monkeys after fetectomy with previous observations in intact pregnant rhesus monkeys at similar stages of gestation.[7]

Material and methods

Care of animals. Fourteen pregnant rhesus monkeys of known gestational age from the California Regional Primate Research Center (Davis, Calif.) were studied. They were acclimated to the laboratory conditions as previously described.[8] Photoperiod in the animal laboratory was 14 hours light and 10 hours dark with lights off at 2 PM. Instrumentation was performed in five control pregnant rhesus monkeys at 99 to 107 days' gestation with a maternal femoral artery and vein catheter and myometrial electromyogram leads. An intrauterine pressure catheter was placed in the uterus through a small incision, as previously described.[9] In a further nine pregnant monkeys surgery was conducted at 121 to 130 days' gestation. In addition to the placement of the above-mentioned instrumentation, the uterine incision was extended to permit removal of the fetus. The fetus was euthanized by exsanguination while it was still under the influence of halothane general anesthesia. The umbilical cord was ligated twice, followed by section between the ties and removal of the fetus, with the placenta left in situ.

The monkeys were maintained postoperatively on a tether-and-swivel system that permitted sampling of maternal blood and recording of myometrial activity.[9] Blood samples for measurement of plasma progesterone levels were taken at three fixed times in relation to the lighting regimen: 4 and 9 hours after the lights went on and 1 hour after the lights went off. The mean value for each day was used for statistical analysis. Plasma estradiol value for each individual animal was the mean of 15 samples taken at 4-hour intervals for 56 hours. Cesarean section was performed with animals under halothane general anesthesia to remove the placenta and terminate the study in five of the monkeys that underwent fetectomy.

Radioimmunoassay procedures. The radioimmunoassays used to measure maternal plasma progesterone and estradiol levels in rhesus monkeys have been described in detail.[10]

Recording and analysis of myometrial electromyogram. Myometrial electromyogram signals were recorded on a computer-based data acquisition system and analyzed both as discrete epochs and also by power spectral analysis for dominant specific sine components as previously described.[7]

Statistical analysis. Results are given throughout as mean ± SD, and the two groups were compared by the two-sample *t* test. Significance was accepted at $p < 0.05$.

Results

Gestational age at the time of delivery of the placenta. In the five control monkeys live fetuses were delivered spontaneously at 165, 159, 159, 167, and 169 (163.8 ± 4.6) days' gestation. In four of the nine monkeys that underwent fetectomy the placenta was delivered vaginally at 185, 193, 201, and 207 days' gestation, after the spontaneous onset of uterine contractions. The placenta was removed by cesarean section at 162, 189, 201, 202, and 219 days' gestation in the other five monkeys that underwent fetectomy. The cesarean section at 162 days was necessary because of prolapse of the stump of the umbilical cord through the cervix,

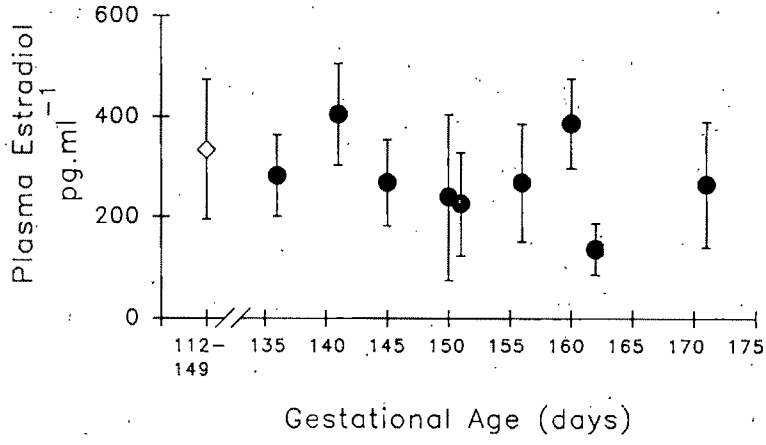

Fig. 2. Plasma estrogen concentration in seven monkeys after fetectomy (●). Each value is mean ± SD of 15 samples taken at 4-hour intervals during 56 hours. For comparison, mean ± SD value for four controls is also shown (◇), with samples over range of 112 to 149 days' gestation.

thereby presenting a risk of intrauterine infection. This animal was not in labor before prolapse. None of the other four monkeys that underwent fetectomy was in labor at the time of elective cesarean section. The gestational age at delivery of the placenta in the group that underwent fetectomy was 195 ± 16.1 days' gestation, which significantly outlasted the duration of pregnancy in the controls ($p < 0.05$).

Maternal arterial plasma progesterone and estradiol concentrations. Plasma progesterone concentrations were well maintained after fetectomy (Fig. 1). At 160 to 169 days' gestation in five animals from which samples were available for progesterone measurement, the plasma progesterone level was 4.2 ± 2.4 ng · ml^{-1}. Maternal plasma estrogen was also well maintained after fetectomy. In the nine animals that underwent fetectomy maternal plasma estradiol (mean over 56 hours) ranged from 282 pg · ml^{-1} at 136 days' gestation to 265.8 pg · ml^{-1} at 171 days (Fig. 2). These values were similar to those found in four control intact rhesus monkeys studied over 112 to 149 days' gestation, 334.6 ± 140 pg · ml^{-1}.

Myometrial activity. In the current study the predominant form of myometrial activity observed before delivery in both groups of monkeys was of the contracture type, which was similar to the activity we observed in >50 intact pregnant rhesus monkeys studied at this stage of gestation and the five controls used in this study. Data from three monkeys that underwent fetectomy and three control monkeys recorded when myometrial activity was in the contracture mode are shown in Fig. 3.

Monkeys that underwent fetectomy did occasionally have contraction-type activity. When this occurred, it happened characteristically during the hours of darkness (Fig. 4) and was clearly distinct from the contracture pattern. In our previous study in pregnant monkeys during contracture activity, power spectral analysis showed the majority of the spectral power (64.7%) below 0.11 cycles · min^{-1}. We designated frequencies <0.11 cycles · min^{-1} as the contracture window. Power spectral analysis was performed on myometrial activity during the night at 30 and 50 days after fetectomy. In eight of the nine animals that underwent fetectomy for which myometrial electromyographic data were available, the myometrial activity present in the contracture window was 61.8% ± 12.9% and 68.1% ± 13.3% at 30 and 50 days after fetectomy, respectively.

We have demonstrated previously that when intact rhesus monkeys go into labor at term there is a switch from contractures to contractions around the time the lights go off in the animal's environment. After a few hours the contractions switch back to contractures. In intact animals the switch from contractures to contractions recurs and intensifies in a 24-hour periodic fashion until delivery eventually occurs (Fig. 5). The switch from contractures to contractions did not show this recurring pattern in fetectomized monkeys in which the placenta was delivered vaginally (Fig. 6).

Placental weight. The placenta weighed 112.8 ± 29.1 gm in the five animals from which it was removed by cesarean section. In the other four animals the placenta was at least partially eaten by the mother and hence the weights were not available. The five fetuses in these pregnancies weighed 338 ± 31.9 gm when removed at fetectomy. According to the data provided by Cheek[11] placental weight can be calculated in the rhesus monkey from the formula: Placental weight = 0.19 (Fetal weight) ± 37.06. With this formula the estimated placental weight at the time the

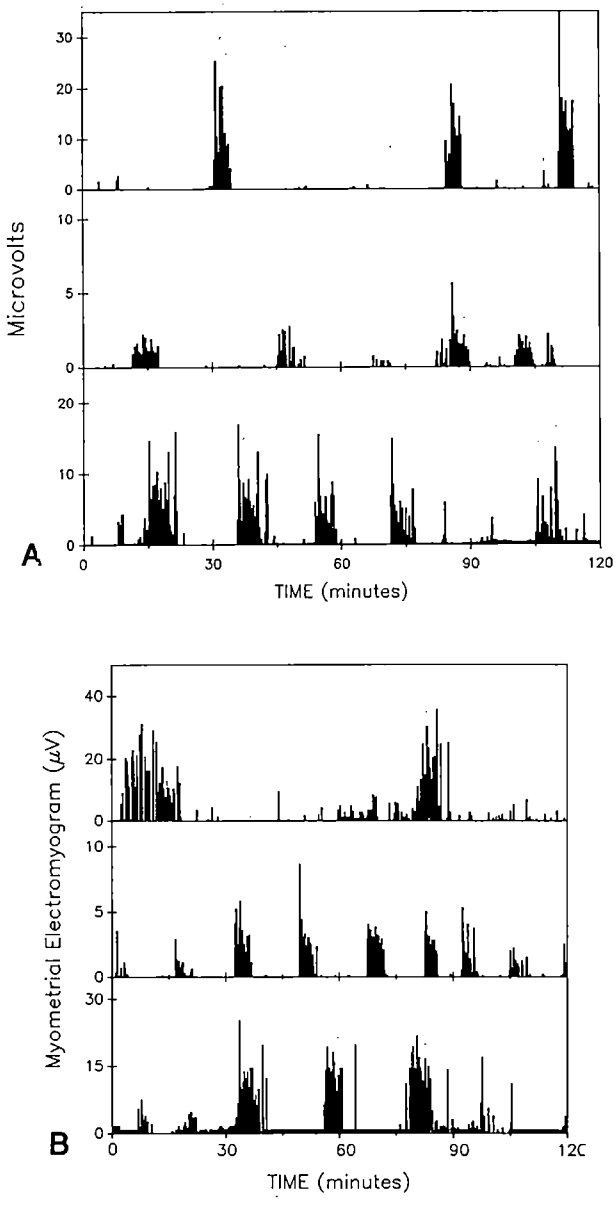

Fig. 3. Myometrial electromyogram recordings to show basic contracture pattern of uterine contractility in three fetectomized monkeys on day 20 after fetectomy **(A)** and three control monkeys **(B)** observed between 141 and 160 days' gestation. Contracture activity was basic form of myometrial activity throughout this period.

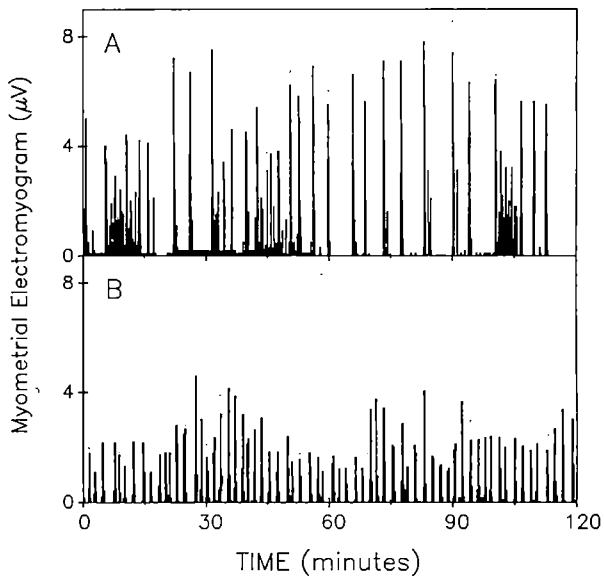

Fig. 4. Similarity of myometrial contraction-type activity as shown by myometrial electromyogram when uterus was in contractions mode in one fetectomized monkey 50 days after fetectomy **(A)** and one control monkey **(B)**.

fetuses were removed would be 101.3 gm. Thus the placentas had remained at about the size they were when the fetus was removed. Placental weights were not available for control monkeys because the mother eats the placenta immediately after vaginal delivery.

Comment

Experiments that clearly define the role of the fetal hypothalamohypophyseal-adrenal axis in the initiation of parturition in the sheep have been difficult to reproduce in nonhuman primates. The nonhuman primate species used for these studies has almost exclusively been the rhesus monkey.[12-14] A major problem in studies that involve intrauterine surgery and fetal instrumentation in this species is the tendency of the monkey to subsequent premature delivery. Therefore comparison of the duration of gestation in pregnant monkeys that have undergone experimental intrauterine surgery on the fetus with the duration of gestation in animals not operated on is less than optimal. This high incidence of premature delivery complicates the evaluation of studies designed to prolong gestation. In the current study we have assessed the fetal role in the determination of the duration of gestation by examining the effect of fetectomy on retention of the placenta and patterns of myometrial activity.

Van Wagenen and Newton[5] performed fetectomy at a very wide gestational age range (70 to 157 days) to investigate the role of the fetus in the initiation of delivery in the pregnant rhesus monkey. In the current study we sought to keep the gestational age at fetectomy within a narrow window (121 to 130 days; approximately 75% of the normal duration of pregnancy, which is 168 days in this species). We chose the window 121 to 130 days' gestation to perform the fetectomy because this period immediately precedes the marked increase in fetal adrenal growth and rise in fetal plasma dehydroepiandrosterone level that precedes birth in the monkey.[15]

When fetectomy data in the available studies in the monkey and other species are compared, it is necessary to take into account the gestational age at which the

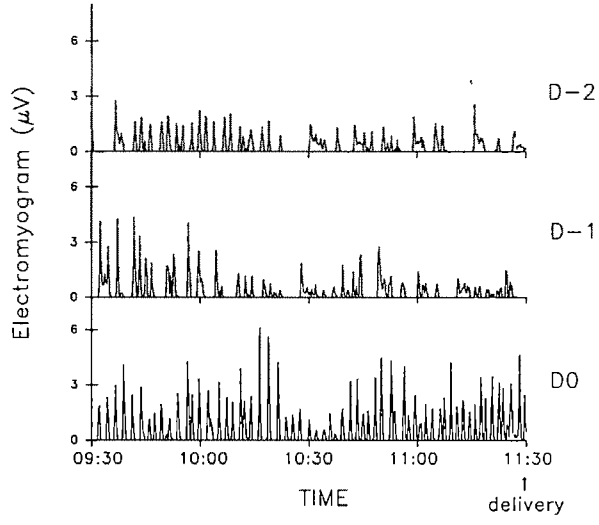

Fig. 5. Myometrial electromyogram from 9:30 to 11:30 PM on day of delivery and two previous nights in intact pregnant rhesus monkey delivered at 165 days' gestation. Lights on at 12 midnight and off at 2 PM. *D-0,* Day of delivery; *D-1* and *D-2,* 1 and 2 days before delivery, respectively.

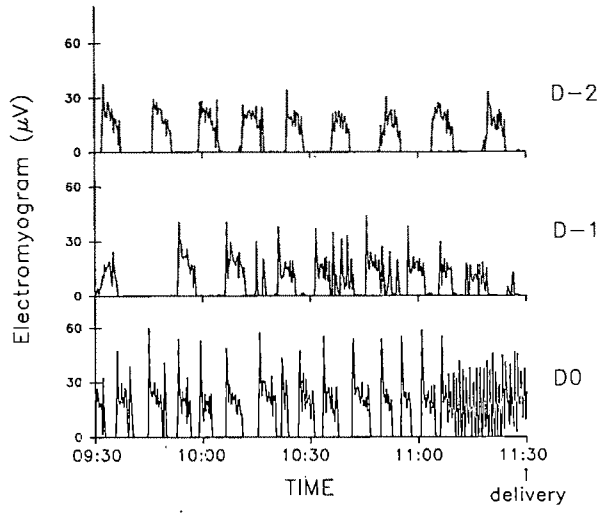

Fig. 6. Myometrial electromyogram from 9:30 to 11:30 PM on day of delivery and two previous nights in monkey after fetectomy that was delivered at 185 days' gestation. Lights on at 12 PM and off at 2 PM. *D-0,* Day of delivery; *D-1* and *D-2,* 1 and 2 days before delivery, respectively.

fetus was removed. In the Van Wagenen and Newton study, in general, the earlier in gestation the fetectomy was performed, the earlier the delivery of the placenta occurred. In another study three monkeys underwent fetectomy at 69 to 73 days' gestation. Fetectomy was followed by spontaneous vaginal delivery of the placenta at 116, 159, and 163 days' gestation.[16] In addition, four monkeys that underwent fetectomy at 107 to 119 days' gestation had the placenta removed by cesarean section at 167, 167, and 169 days, corresponding to the time of normal spontaneous delivery in the rhesus monkey. Thus information on when these placentas could have delivered spontaneously is lacking.[16]

In our studies the placenta remained viable as demonstrated by maternal plasma progesterone (2 to 5 ng · ml^{-1}) and estradiol (250 to 500 pg · ml^{-1}) concentrations that were within the normal midpregnancy range for intact animals in our laboratory and that of others.[17] The weights of the five placentas we were able to measure were maintained at the level they would have been at the time of fetectomy.[11] Normal maternal progesterone concentrations have been observed in all fetectomy studies to date in the rhesus monkey.[16] Tullner and Hodgen[16] demonstrated a fall in maternal estradiol level in one pregnant rhesus monkey that underwent fetectomy at 73 days' gestation and one at 116 days' gestation. In contrast, Dorfman and van Wagenen[18] found no significant change in urinary estrogen excretion after fetectomy.

It is important to compare our findings on placental retention and estrogen and progesterone plasma concentrations in the rhesus monkey after fetectomy with observations made by Albrecht et al.[19-22] in another nonhuman primate species, the baboon, after fetectomy. Both similarities and differences exist. Studies in both species agree that the placenta remains viable after fetectomy[19-22] as determined by the ability of the placenta to convert androgens to estrogen.[19] However, after fetectomy in the baboon at midgestation, maternal estradiol concentrations fall to low or undetectable levels. This observation suggests that in the absence of the fetus the supply of C19 precursors to the placenta is inadequate. The current studies in rhesus monkeys that underwent fetectomy at 75% of gestation show that adequate maternal precursors are available to maintain estrogen concentrations at the level present at the time of fetectomy. The most likely source of androgenic precursors for estrogen production in the monkey after fetectomy is the maternal adrenal. The failure of maternal estrogens to rise after 155 days' gestation supports the view that the fetus provides the precursors for the normal prepartum increase in maternal estrogens.

In the pregnant baboon maternal progesterone falls 64% to 80% after fetectomy.[20] In contrast, maternal progesterone levels were maintained within the normal pregnancy range in the rhesus monkey after fetectomy in both our study and that of others.[16] After fetal death in pregnant women, the maternal progesterone level is maintained although maternal estrogen production decreases.[23] Whether the continued production of progesterone in the rhesus monkey is due to a rejuvenated corpus luteum or maintained placental function remains to be determined. In any event our study dem-

onstrates that in the rhesus monkey, after fetectomy but with retention of the placenta, plasma progesterone and estrogen concentrations are maintained well above nonpregnant levels and within the midpregnancy range. In the baboon after fetectomy in midpregnancy the placenta is delivered at term. Administration of estrogen to the baboon after fetectomy will maintain maternal progesterone concentrations and results in the retention of the placenta in utero past the normal length of gestation.[21, 22] Thus the differences in progesterone production after fetectomy in the monkey and baboon may be determined in large measure by differences in estrogen production. These interesting differences after fetectomy between the baboon and the monkey merit further investigation.

None of the previous studies involving fetectomy have been conducted in chronically instrumented animals to permit continuous evaluation of myometrial activity. In the current study we observed that myometrial activity after fetectomy in the monkey throughout the period of observation consisted almost entirely of long-lasting, contracture-type myometrial epochs. This type of myometrial activity is the predominant form of myometrial contractility that may be observed during pregnancy in the rhesus monkey[7] and baboon.[24] In monkeys after fetectomy contractures switch to contractions when the placenta is delivered. As with intact pregnant rhesus monkeys, this switch occurs around the time the lights go off in the animal's environment. However, the frequency of recurrence of the shift from contracture to contraction patterns is less and its amplitude less pronounced when monkeys that have undergone fetectomy are delivered, compared with intact monkeys.

In summary, after fetectomy in the pregnant rhesus monkey at 120 to 130 days' gestation, the placenta may be retained as long as 45 days after the average duration of pregnancy in controls. These results support the concept that the fetus plays a role in determining the length of gestation in this nonhuman primate species.

We thank Karen Moore for her help with the manuscript and Susan Jenkins for assistance with the analysis of the myometrial electromyography data.

OBJECTIVE: Women who smoke have impaired fertility and experience menopause at an earlier age. This experiment determined the effect of benzo(a)pyrene, a polycyclic aromatic hydrocarbon contained in cigarette smoke, on murine ovarian volume, total corpora lutea volume, individual corpora lutea volumes, and corpora lutea numbers.

STUDY DESIGN: C57BL/6N mice were treated with intraperitoneal injections of 0 to 500 mg/kg benzo(a)pyrene in corn oil. The 20 mice at each dose were divided into four groups of five each and were killed at 1, 2, 3, or 4 weeks after treatment. Ovaries were serially sectioned and analyzed morphometrically.

RESULTS: Benzo(a)pyrene produced a dose- and time-dependent decrease in ovarian volume, total corpora lutea volume, and number of corpora lutea per ovary. This effect was transitory at low doses with complete recovery of corpora lutea by 4 weeks. Compensatory hypertrophy of the individual corpora lutea occurred during the recovery phase. Ovarian function did not return in animals treated with the two highest doses.

CONCLUSION: Benzo(a)pyrene is a murine ovarian toxicant that inhibits corpus luteum formation in a dose- and time-dependent fashion. (AM J OBSTET GYNECOL 1992;166:1535-41.)

Key words: Corpora lutea, ovary, smoking, polycyclic aromatic hydrocarbons

There is a growing weight of evidence that suggests that women who smoke have impaired fecundity, an increased risk for infertility, and a younger age at menopause. Available data exploring these adverse reproductive effects with epidemiologic techniques suggest that many, if not all, of these adverse outcomes are cigarette dose related. Recently these adverse reproductive effects of smoking have been thoroughly reviewed.[1]

Cigarette smoke is a highly complex mixture containing approximately 4000 identified compounds.[2] Those that have attracted the greatest attention produce toxic effects in organ systems other than the reproductive tract. These compounds include carbon monoxide, nicotine, and chemicals contained in the tar fraction, including polycyclic aromatic hydrocarbons. Previous investigations in this and other laboratories have explored the effect of individual components of cigarette smoke on reproductive function in experi-

mental animals.[1] Our attention has focused on the impact of polycyclic aromatic hydrocarbons on ovarian function; we have demonstrated that some of these hydrocarbons can destroy follicles and impair fertility in mice.[1, 3, 4] Recent investigations have suggested that the impact of polycyclic aromatic hydrocarbons on impaired fertility is a result of an alteration in ovulatory frequency.[4] To further investigate this impact on ovulatory frequency, we have conducted a series of studies designed to characterize the effect of benzo(a)pyrene, a common environmental polycyclic aromatic hydrocarbon and major constituent in cigarette smoke, on total ovarian volume, total corpora luteal volume, the number of corpora lutea per ovary, and the volumes of individual corpora lutea at 1, 2, 3, and 4 weeks after treatment with varying doses.

Material and methods

A total of 140 weanling C57BL/6N mice were obtained from the National Institutes of Health veterinary resources branch. Animals were maintained in the laboratory for approximately 1 week to allow acclimation. Care and use of animals conformed to the guidelines established by the animal care committee. Animals were divided into groups of 20 and injected with one of seven doses of benzo(a)pyrene, 0, 1, 5, 10, 50, 100 or 500 mg/kg. Doses were given in corn oil intraperitoneally, such that a 20 gm mouse received 1 ml corn oil. Each dosage group was then subdivided into groups of five. These subgroups of animals were killed at 1, 2, 3, or 4 weeks after treatment. Then the ovaries were removed and fixed for 24 hours in Bouin's fixative. They were then placed in 70% ethanol until embedding, serially sectioned at 5 μm, and stained with hematoxylin and eosin.

All volume measurements were made with a Bioquant IV morphometric system (R and M Biometrics, Inc., Nashville). The area of each ovary and corpora lutea was determined by circumscribing these structures in every tenth section. Ovarian volume was calculated with the following equation:

Ovarian volume (cubic millimeters) = Sum of section areas (in square millimeters) × 0.005 mm × 10

Volume measurements of individual corpora lutea and total corpora luteal volume per ovary were calculated with similar formulas. Statistical analysis was performed with one-way analysis of variance to compare the effect of varying doses of benzo(a)pyrene versus control at each week tested. When analysis of variance was used, the level of significance was noted by p, with values <0.05 considered significant. The unpaired Student t test was used to determine the significance of the effect of each individual dose. Because multiple comparisons were used, the Bonferroni correction was used to reduce the risk of type I error. Level of significance was noted by p with values <0.01 considered significant.

Results

Total ovarian volume. Over the 4-week period of the experiment, total control ovarian volume ranged from 0.8 to 0.9 mm^3 (Table I). One week after exposure, when varying doses were compared with control, benzo(a)pyrene significantly reduced ovarian volume ($p < 10^{-6}$). Compared with control ovarian volume, the 16% reduction in ovarian volume after 1 mg/kg benzo(a)pyrene was not significant. The remaining doses of 5 to 500 mg/kg produced highly significant ($p < 10^{-5}$), dose-dependent reductions in ovarian volume ranging from 67% to 35% of control. Two weeks after exposure, mean ovarian volume in mice treated with 5 or 10 mg/kg benzo(a)pyrene had returned to control levels. When varying doses were compared with control by analysis of variance, the benzo(a)pyrene-induced reduction in ovarian volume ($p < 10^{-6}$) remained significant among mice treated with benzo(a)pyrene at doses of 50, 100, and 500 mg/kg ($p < 0.01$, 10^{-6}, and 10^{-6}, respectively). The effect of

§$p < 0.05$.

the 1 mg/kg dose appeared significant ($p < 0.05$), but because p was not <0.01, this effect was not significant after the Bonferroni correction. Three and 4 weeks after exposure, when varying doses of benzo(a)pyrene were compared with control by analysis of variance, the benzo(a)pyrene-induced reduction in ovarian volume ($p < 10^{-5}$ and 10^{-6}, respectively) was significantly different from control only in the animals treated with the two highest doses, 100 mg/kg ($p < 0.05$ and 0.0001, respectively) and 500 mg/kg ($p < 10^{-4}$ and 10^{-6}, respectively). The apparent significance of the 100 mg/kg dose at week 3, however, was not maintained after the Bonferroni correction was applied.

Total corpora lutea volume. There appeared to be greater variation in total corpora lutea volume over the 4 weeks of this experiment than in total ovarian volume (Table II). Control corpora lutea volume ranged from 0.19 to 0.06 mm^3 over the 4 weeks. The lowest dose tested, 1 mg/kg, had no effect on corpora lutea volume, whereas the highest dose tested, 500 mg/kg, completely prevented corpora lutea formation. One week after exposure benzo(a)pyrene at doses >1 mg/kg effectively disrupted corpora lutea formation. Total corpora lutea volumes ranged from 0 to 0.01 mm^3, a highly significant reduction when compared with control by analysis of variance ($p < 10^{-6}$). A significant reduction in total volume persisted at 2 and 4 weeks after exposure, when all doses were compared with control by analysis of variance ($p < 0.002$ and 10^{-4}, respectively). Animals killed 2 weeks after benzo(a)pyrene exposure displayed a dose-dependent reduction in total volume at doses >10 mg/kg. The reductions were significant when compared with control for the 50, 100, and 500 mg/kg doses ($p < 0.01$, 0.001, and 0.001, respectively). Four weeks after treatment only the two highest doses, 100 and 500 mg/kg, produced a significant reduction in total volume ($p < 0.002$ and 0.01, respectively). Because of the relatively small corpora lutea volumes in the week 3 control animals, only the highest dose resulted in a significantly smaller volume than the control animals ($p < 0.01$).

Individual corpora lutea volume. Among control animals individual corpora lutea volumes varied from 0.023 to 0.039 mm^3 over the 4 weeks of this experiment (Table III). Individual corpora lutea volume, where corpora lutea were present an an ovary, appeared to be maintained 1 week after benzo(a)pyrene injection. At 2, 3, and 4 weeks after benzo(a)pyrene injection, there was a significant increase in mean individual corpora lutea volume in injected animals versus controls ($p < 10^{-4}$, 0.02, and 10^{-5}, respectively). This increase in individual volume was significant when corpora lutea formation recovered in the two lowest doses at week 2 ($p < 0.01$), all but the 5 mg/kg dose at week 3 ($p < 0.01$-0.001), and all but the 1 mg/kg dose at week 4 ($p < 0.01$ to 0.001).

Corpora lutea number. Over the course of the experiment total corpora lutea number in control animals varied from 2.5 to 5 corpora lutea per ovary (Table IV). When analysis of variance was used to compare the effect of multiple doses versus control at each week, there was a significant reduction in corpora lutea per ovary at 1, 2, 3, and 4 weeks afer benzo(a)pyrene treatment ($p < 10^{-6}$, 0.002, 0.02, and 10^{-4}, respectively). The highest dose, 500 mg/kg, completely prevented corpora lutea formation, whereas the lowest dose, 1 mg/kg, had no significant effect on corpora lutea numbers.

One week after benzo(a)pyrene treatment, doses ≥5 mg/kg disrupted corpora lutea formation, with only 0 to 0.5 corpora lutea per ovary ($p < 0.001$). By 2 weeks animals treated with benzo(a)pyrene at doses of 5 or 10 mg/kg began to recover their ability to form corpora lutea; however, the three highest doses, 50, 100, and 500 mg/kg, still exhibited a significant reduction in corpora lutea numbers ($p < 0.005$, 0.001, and 10^{-4}, respectively). Three weeks after treatment, recovery in corpora lutea number had occurred in all animals but

those injected with the two highest doses. A reduction in corpora lutea numbers persisted 3 and 4 weeks after treatment with 100mg/kg ($p < 0.05$ and 0.0005, respectively) and 500 mg/kg ($p < 0.002$ and 0.001, respectively). It should be noted that the effect of the 100 mg/kg dose was not significant at 3 weeks after the Bonferroni correction was applied.

Comment

Data among humans demonstrate that smoking impairs fertility. For example, studies by Baird and Wilcox[5] demonstrate that among women who are able to become pregnant within 2 years after stopping contraception the time to conception was considerably longer among smokers than nonsmokers. This effect appeared to be independent of socioeconomic status, history of reproductive disease, frequency of intercourse, and other factors previously identified as being associated with impaired fertility. A study of a different design by Vessey et al.[6] explored time to delivery among a group of women after cessation of contraception. This study demonstrated that the number of months until delivery of a child increased as a function of the number of cigarettes consumed.

In addition, an investigation conducted by MacMahon et al.[7] demonstrated that urinary estrogens during the luteal phase of the cycle were lower among smokers than nonsmokers. These data, collected in humans, suggest that if smoking impairs fertility, an impact on corpora lutea function may be responsible in part for this effect. Longcope and Johnston[8] reported no difference in serum levels of estrone and estradiol in premenopausal smokers versus controls. They suggested that the data of MacMahon et al.[7] indicate altered metabolism of estrogens rather than decreased production. Unfortunately, two factors may confound their data and make this conclusion premature. They failed to control for the menstrual cycle day when estrogens were measured. Given the large fluctuations in estrogens throughout the cycle, changes in estrogen production could easily be missed. In addition, the reduction in estrogen excretion reported by MacMahon et al. occurred only in the luteal phase. Follicular phase estrogen excretion was normal. This makes the failure of Longcope and Johnston to control for cycle day even more critical. It is also unlikely that estrogen metabolism would be radically different in the luteal versus follicular phase. Furthermore, the average daily consumption of cigarettes by the smoking group, although >10 per day, is not reported in detail. If cigarette smoking alters ovarian estrogen production in a dose-dependent fashion, this effect may be seen only in a group of heavy smokers. Given the limitations of this study, the effect of smoking on corpora lutea estrogen production is unclear.

In spite of the complex composition of cigarette smoke, however, no studies in humans to date have suggested the component (or components) contained in cigarette smoke that may be responsible for the adverse effects of smoking on reproductive performance. To further explore these issues we have conducted studies that have evaluated the impact of one smoke component on ovarian function in experimental animals. The focus of our experimental investigations has been the polycyclic aromatic hydrocarbons, a family of compounds contained in both direct and sidestream smoke. A recent report estimates the amount of benzo(a)pyrene in the mainstream smoke from a nonfilter cigarette to range from 20 to 40 ng. Up to 460 ng/hr can be inhaled in an environment containing cigarette smoke.[2] Previous investigations have demonstrated that exposure to polycyclic aromatic hydrocarbons destroys oocytes in murine ovaries.[9-12] This occurs in a time- and dose-dependent fashion and appears also to be a function of the strain and species of experimental animal used for the studies. In addition, previous studies have demonstrated that benzo(a)pyrene decreases fertility in rodents by decreasing ovulatory

number and corpora lutea number.[4] The data presented in this study further define the impact of benzo(a)pyrene on ovulation and corpora lutea formation in mice.

Total ovarian volume, a composite measure reflecting the volume of growing follicles, antral follicles, corpora lutea, and stromal tissue, was reduced in both a time- and dose-dependent fashion in these studies. Corpora luteal volume averaged 14% of total ovarian volume in this study, consistent with the 17% previously reported from our laboratory.[13] To further define the effect of benzo(a)pyrene on corpora lutea, the dominant structure in the ovary after ovulation, we evaluated total corpora lutea volume, corpora lutea number, and individual corpora lutea volume. Over the 4-week course of this experiment there was a substantial reduction in number, which was both dose and time dependent. Interestingly, at 1 week after treatment, reductions in volume were seen at low doses of benzo(a)pyrene (5 mg/kg). Animals treated with doses of ≥100 mg/kg appeared to have a reduction in number throughout the course of this experiment. However, those animals treated wtih doses <100 mg/kg appeared to recover their ability to produce corpora lutea by the second to fourth week of this experiment.

It is of interest to note that if corpora lutea were present, individual corpora lutea volume did not decrease after benzo(a)pyrene administration. In fact, with recovery of the ability to form corpora lutea, individual corpora lutea after benzo(a)pyrene were significantly larger than control corpora lutea. This effect was seen even with the lowest dose studied (1 mg/kg). This compensatory hypertrophy of individual corpora lutea after recovery from benzo(a)pyrene is unable to compensate for the loss in number, however, and total volume is not maintained. Thus the fall in total corpora luteal volume in this experiment in a both dose- and time-dependent fashion is due to the reduction of corpora lutea number. Given the reduction in luteal urinary estrogens observed by MacMahon et al.[7] in female smokers, it is interesting to speculate that the reduction in total corpora lutea volume in these mice may result in reduced estrogen production. The lowered estrogen levels may result in reduced feedback at the pituitary and result in the individual corpora luteal hypertrophy. This concomitant increase in individual corpora lutea volume precludes proposing any hypothesis about corpora lutea estrogen production in a species, such as humans, that produces only one corpus luteum per cycle.

These data demonstrate more clearly the adverse impact of polycyclic aromatic hydrocarbons on ovarian function and corpora lutea formation. Even at doses of benzo(a)pyrene as low at 5 mg/kg reductions in total corpora lutea volume and number were observed in animals killed 1 week after exposure. There was a nonsignificant trend toward reduction of these parameters at the lowest dose used (1 mg/kg). Given that the reproductive system is dynamic and that benzo(a)pyrene is cleared from the animal over a period of several days, it is not surprising that there was resumption in corpora lutea formation over the 4-week duration of the experiment. The sensitivity of the ovary, however, to these low doses is of considerable interest because these doses, 1 to 5 mg/kg, appear to be substantially lower than the doses of polycyclic aromatic hydrocarbons responsible for induction of microsomal monooxygenases or other forms of toxicity, including carcinogenicity, that are typically ascribed to the polycyclic aromatic hydrocarbons.[14]

Two mechanisms may be responsible for the impairment in corpora lutea formation observed in this study. The antral follicle may rupture, but the granulosa cells may not luteinize because their function is impaired by benzo(a)pyrene, thus inhibiting corpora lutea formation. The ability of the benzo(a)pyrene-exposed ovaries to form a reduced number of hypertrophic corpora lutea before the recovery of corpora

lutea number and total volume suggests this cannot be the only mechanism. A more likely explanation is that corpora lutea formation is impaired because benzo(a)pyrene has destroyed follicles that would eventually mature, ovulate, and become luteinized to form corpora lutea. This hypothesis is supported by previous experiments that demonstrate that benzo(a)pyrene reduces follicle numbers in mice.[3]

The time- and dose-dependent loss in total corpora lutea volume and numbers (Tables II and IV) suggests which follicle types are destroyed by a given dose of benzo(a)pyrene. The recovery of corpora lutea formation by 2 weeks in the 5 mg/kg group suggests a direct effect on antral follicles. Corpora lutea formation was disrupted for 2 to 3 weeks in the 10 to 50 mg/kg groups. This suggests a direct effect on growing follicles, because primordial follicles require 21 days to reach the antral stage. All follicle types from primordial to antral are affected by the 100 and 500 mg/kg dose because the effect is immediate and persists past the length of time required for surviving primordial follicles to ovulate.

It should be pointed out that there are two potentially confounding factors in the design of this study. Intraperitoneal injections of the toxicant may allow direct uptake of large doses into the ovary and, hence, greatly increase toxicity. This effect is unlikely, however. Recent investigations in our laboratory demonstrated that direct intraovarian injection of benzo(a)pyrene caused no effect on corpora lutea formation in this strain of rodents. In contrast, intraovarian injection of several metabolites of benzo(a)pyrene resulted in inhibition of corpora lutea formation (unpublished data). In addition, previous experiments have demonstrated that it is possible to block the toxicity of benzo(a)pyrene to resting follicles with α-naphthoflavone, a compound that blocks the metabolism of benzo(a)pyrene.[15] This suggests that direct benzo(a)pyrene toxicity or intraovarian metabolism of benzo(a)pyrene is not an important aspect in its systemic toxicity on corpora lutea formation.

In addition, we did not control for cycle day or confirm the animals were cycling before injection. Previous studies have demonstrated that benzo(a)pyrene persists in these rodents for at least 7 to 10 days.[16-19] Because the compound persists for such a long time, at least two ovarian cycles in these rodents, we have assumed that cycle day of treatment is of little importance. The consistency and high degree of significance achieved in this study support this assumption because failing to control for cycle day should bias the results away from significance. The fact that fresh corpora lutea were identified in these animals at all time points, although frequently in reduced numbers, confirms that these animals indeed were ovulating.

Although reversibility of the benzo(a)pyrene-induced reduction of corpora lutea volume and number at doses <100 mg/kg suggests that there is resilience in the reproductive system, complete recovery is unlikely. The data in this investigation are consistent with the considerable destruction of resting and growing follicles by these doses of polycyclic aromatic hydrocarbons previously observed in studies by our group and others. The correlation between follicle numbers and the age at onset of reproductive failure[20] suggests that the total reproductive life span would be reduced in these animals.

We thank Robert Walls, PhD, for his expert assistance with the statistical analysis.

The mechanisms of preterm labor: Common genital tract pathogens do not metabolize arachidonic acid to prostaglandins or to other eicosanoids

Phillip R. Bennett, BSc, MD, and Murdoch G. Elder, MD
London, England

OBJECTIVE: Our aim was to determine the ability of pathogens commonly associated with genital tract infection and preterm labor to incorporate arachidonic acid and to metabolize it to prostaglandins or to other eicosanoids.
STUDY DESIGN: Four common genital tract pathogens, *Escherichia coli, Streptococcus viridans, Bacteroides fragilis*, and a group B β-hemolytic streptococcus, were incubated with tritium-labeled arachidonic acid for 2 to 48 hours. Uptake of arachidonic acid was calculated from uptake of radioactivity into the organisms. Tritium-labeled arachidonic acid within the medium was separated from any metabolites by high-performance liquid chromatography to assess metabolism of arachidonic acid within the bacteria.
RESULTS: Although all organisms were able to take up arachidonic acid, analysis of its metabolism with high-performance liquid chromatography demonstrated that none of these organisms will synthesize cyclooxygenase, lipoxygenase, or epoxygenase products.
CONCLUSION: Bacterial infection cannot initiate preterm labor by intrinsic biosynthesis and release of prostaglandins or other eicosanoids by the bacteria themselves. (Am J Obstet Gynecol 1992;166:1541-5.)

Key words: Preterm labor, infection, bacteria, arachidonic acid, prostaglandins, eicosanoids

There is a clear association between genital tract infection and the onset of labor before term.[1] Labor at term is associated with an increase in arachidonic metabolism within the uterus, in particular, within the amnion and decidua.[2] In amnion there is an increase in both cyclooxygenase metabolism and lipoxygenase metabolism, but the increase in cyclooxygenase metabolism predominates, producing a large increase in the synthesis of prostaglandin E_2 (PGE_2).[3] A similar increase in amnion prostaglandin synthesis has been demonstrated in association with preterm labor in the presence of infection.[4] Various hypotheses have been proposed for the mechanism by which bacterial infection increases arachidonic acid metabolism within the uterus. It has been suggested that release of phospholipases or endotoxins by bacteria may stimulate prostaglandin synthesis in the fetal membranes, or that a similar effect might be mediated by cytokines produced by inflammatory cells.[3, 5, 6]

Most attention has focused on the role of the cycloox-

Table I. Retention data for arachidonic acid metabolites on reverse-phase high-peformance liquid chromatography

Compound	*Retention time (min)*	*Peak width (min)*
6-Keto-prostaglandin $F_{1\alpha}$	8.0	7.0-9.0
Thomboxane B_2	11.0	10.5-12.0
Prostaglandin $F_{2\alpha}$	13.0	12.5-14.5
PGE_2	16.5	15.5-18.0
13,14-Dihydro-15-keto-prostaglandin $F_{2\alpha}$	22.0	Not determined
13,14-Dihydro-15-keto-prostaglandin E_2	27.0	28.0-28.5
Prostaglandin A_2	29.0	Not determined
Prostaglandin B_2	31.5	Not determined
Leukotriene B_4	34.0	34.0-35.0
5-Hydroxyeicosatetraenoic acid (two peaks)	35.5	34.5-36.5
	43.0	42.0-44.0
11-Hydroxyeicosatetraenoic acid	42.5	43.0-44.0
12-Hydroxyeicosatetraenoic acid (two peaks)	35.5	35.0-36.0
	42.0	41.5-43.0
15-Hydroxyeicosatetraenoic acid	42.0	41.5-43.0
14,15-Hydroxyeicosatetraenoic acid	47.0	Not determined
Arachidonic acid	58.0	57.5-58.5

ygenase products of arachidonic acid, the PGs, in the initiation of preterm labor. Arachidonic acid can, however, be metabolized by lipoxygenase and epoxygenase enzyme pathways.[3, 7] The roles of these compounds in pregnancy and labor are not, at present, well understood, although we have shown that 5-hydroxyeicosatetraenoic acid is oxytocic.[8] Little attention has been paid to the possibility that the bacteria themselves might metabolize arachidonic acid to oxytocic compounds. Lipid fractions of *Propionibacterium acnes* have been found to have prostaglandin-like activity in bioassay, although production of prostaglandins cannot be demonstrated.[9] Gulbis et al.[10] originally reported production of PGE_2 by *Escherichia coli*. This appeared to be dependent on the presence of exogenous arachidonic acid and was inhibited by indomethacin. The same group later reported similar experiments[11] in which production of PGE_2 appeared to be independent of the presence of bacteria and in which indomethacin had no consistent effect. They concluded that their earlier work had been unreliable and that *E. coli* does not appear to synthesize prostaglandins.

We have therefore performed a series of experiments to determine whether common genital tract pathogens are able to take up exogenous arachidonic acid and whether they are able to syntheize cyclooxygenase, lipoxygenase, or epoxygenase metabolites.

Methods

Bacterial preparations. Single, pure colonies of laboratory stock isolates of four common genital tract pathogens, *E. coli, Streptococcus viridans, Bacteroides fragilis*, and a group B β-hemolytic streptococcus, were picked and incubated overnight at 37° C in a suitable medium (Oxoid No. 2 broth or Difco Thiol broth). This resulted in 10^8 organisms per milliliter of medium. The organisms were sedimented by centrifugation at 3000 rpm for 10 minutes and the medium was poured off. Fresh culture medium containing 0.2 μCi/ml tritium-labeled arachidonic acid was added to the organisms, and they were gently resuspended. The suspensions were divided into five aliquots of 10 ml each and incubated at 37° C.

Aliquots of suspensions of each of the organisms were incubated for 2, 4, 8, 24, and 48 hours. The organisms were then removed by centrifugation and filtration, and the bacterial pellet was retained to allow incorporated and unreleased radioactivity to be measured. Four milliliters of culture medium from each aliquot was stored at −20° C until further analysis. The remaining 1 ml of culture medium was added to scintillation fluid (Unisolve-1, Koch-Light, Ltd.) in the ratio 1:4, and radioactivity was counted to allow calculation of tritium-labeled arachidonic acid uptake by the bacteria. Each experiment was performed five times. Further experiments were performed in which the tritium-labeled arachidonic acid was supplemented by unlabeled arachidonic acid (10^{-9} mol/L) to determine the effect of concentration on uptake.

Control experiments were performed with bacterial culture medium containing 0.2 μCi/ml of tritium-labeled arachidonic acid without organisms.

Analysis of arachidonic acid metabolism by high-performance liquid chromatography. Each 4 ml aliquot of medium was acidified to pH 3.15 with formic acid and passed through a prepared C18 SepPak (Waters Associates), and the tritium-labeled arachidonic acid metabolites were eluted into 5 ml of methyl formate. The solvent was evaporated with oxygen-free nitrogen, and the residue was redissolved in 1 ml of 30% (vol/vol) acetonitrile in 40 mmol/L triethylamine formate. The fatty acids were then separated according to

polarity with a high-pressure liquid chromatography system based on a reverse-phase fatty acid analysis column. The initial solvent mixture was 30% acetonitrile in 40 mmol/L triethylamine formate, increasing to 50% and 100% acetonitrile after 25 and 52 minutes, respectively. The solvent flow was 1 ml/min, and 500 μl fractions were collected for a total of 60 minutes. Each fraction was dissolved in 4 ml of scintillation fluid, and radioactivity was counted in an Intertechnique SL3000 liquid scintillation counter. The radioactivity present in each metabolite peak in the chromatograms was calculated by summation.

We have previously reported the elution times for a wide range of arachidonic acid metabolites with this system[3, 7, 12] (Table I). Experiments have been performed in which radiolabeled prostaglandin $F_{2\alpha}$ and PGE_2 were added exogenously to culture medium to determine their recovery from the incubation medium. Recovery of these two compounds was found to be 94% (SD 2.3%) and 79% (SD 1.6%), respectively.[12]

Results

Each of the organisms incorporated tritium-labeled arachidonic acid, and the rates of incorporation and the total uptake were similar for all of the organisms. At 2, 4, 8, 24, and 48 hours, 21%, 32%, 38%, 52%, and 61%, respectively, of tritium-labeled arachidonic acid had been incorporated into the bacterial cells. Addition of unlabeled arachidonic acid had no effect on the proportion of tritium-labeled arachidonic acid taken up into the cells.

No significant peaks of radioactivity were detected at retention times corresponding to cyclooxygenase products in either experimental or control incubates. Significant peaks were detected at retention times corresponding to dihydroxyeicosatetraenoic acid and monohydroxyeicosatetraenoic acid (34, 35, and 42 minutes) and arachidonic acid (57.5 minutes) (Fig. 1). There was an increase in radioactivity corresponsing to dihydroxyeicosatetraenoic acid and monohydroxyeicosatetraenoic acid in both experimental and control incubates with increasing incubation time; however, this increase was significantly greater ($p < 0.01$) in control incubates (Fig. 2). There was a significant decrease in radioactivity corresponding to arachidonic acid in experimental incubates when compared with controls ($p < 0.01$) (Fig. 2).

Comment

Preterm labor remains a significant problem in obstetric practice. It accounts for up to 10% of all births but 85% of perinatal deaths in otherwise normal babies.[13] Although in many cases the cause of preterm labor remains obscure, there is a growing body of evidence that genital tract infection may play a role in

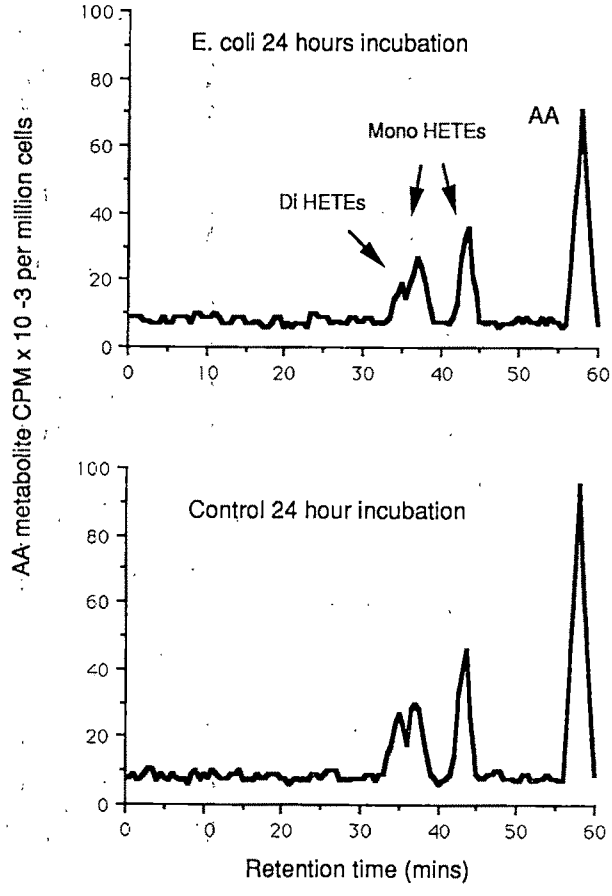

Fig. 1. Representitive high-performance liquid chromatography chromatograms showing tritium-labeled arachidonic acid metabolites found in culture after incubation of tritium-labeled arachidonic acid with *E. coli* for 24 hours *(top)* compared with control, sterile incubation. *AA*, Arachidonic acid; *HETE*, hydroxyeicosatetraenoic acid.

many cases. Several authors have reported an association between preterm rupture of membranes and maternal infection.[14] Others have demonstrated an association between preterm labor and infection with intact membranes, both with and without signs or symptoms of infection.[15] There is now a large body of evidence that an increase in prostaglandin synthesis within the uterus is an important early event in the onset of human parturition at term.[16] Labor is associated with increased synthesis of prostaglandins by the fetal membranes, in particular, the amnion. Curbello et al.[17] have found a high concentration of prostaglandin precursor arachidonic acid in amnion epithelial cells. In association with labor arachidonic acid metabolism in amnion increases with a large increase in the synthesis of PGE_2 and a smaller increase in metabolism through the lipoxygenase enzyme pathway to monohydroxyeicosatetraenoic acid and dihydroxyeicosatetraenoic acid and leukotriene B_4.[1, 2] Although the prostaglandins are known to be oxytocic and to mediate cervical ripening, little is

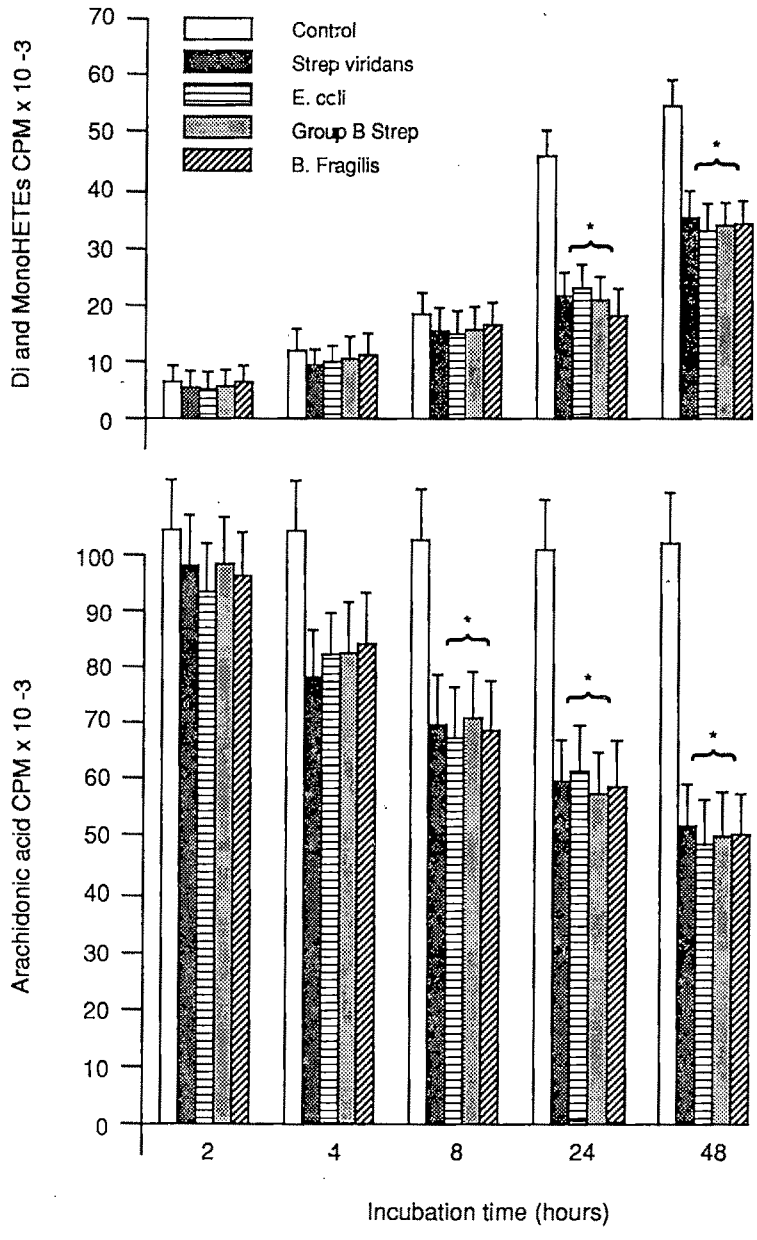

Fig. 2. Tritium-labeled arachidonic acid and dihydroxyeicosatetraenoic acid and monohydroxyeicosatetraenoic acid *(HETE)* found in culture medium after incubation of tritium-labeled arachidonic acid with various organisms between 2 and 48 hours. known about the roles of the lipoxygenase metabolites of arachidonic acid. 5-Hydroxyeicosatetraenoic acid appears to be weakly oxytocic[7] and may play a role in the mediation of physiologic prelabor contractions.[18] Several substances found in amniotic fluid have been postulated to be fetally derived stimulators of arachidonic acid metabolism in the amnion; current candidates include platelet-activating factor[19] and interleukin-1β [20] Lopes-Bernal et al.[4] have reported a marked increase in PGE and leukotriene B_4 production from the amnion of preterm deliveries associated with chorioamnionitis, when compared with idiopathic preterm labor. Several theories have been proposed for the mechanism whereby infection increases prostaglandin synthesis by the amnion. Lamont et al.[21] and Bennett et al.[3] have shown that pathogenic bacteria release phospholipase, which causes changes in the metabolism of arachidonic acid in amnion similar to those changes seen with labor at term. Romero et al.[6, 20] suggest that it is the production of cytokines by inflammatory cells that stimulates prostaglandin synthesis by amnion.

In vitro studies of the effect of chorioamnionitis on

arachidonic acid synthesis have generally concentrated on the production of prostaglandins by the amnion. Little attention has been focused on the possibility that bacteria themselves may make prostaglandins or other eicosanoids. In this study we have investigated the ability of four common genital tract pathogens to metabolize exogenous arachidonic acid by cyclooxygenase, lipoxygenase, or epoxygenase enzyme pathways.

Although each of the organisms tested took up and incorporated arachidonic acid, there was no evidence that any of the four is able to metabolize that arachidonic acid by cyclooxygenase enzyme pathways to produce prostaglandins. Similarly there was no evidence of metabolism of arachidonic acid through epoxygenase enzyme pathways. Conversion of arachidonic acid to compounds that cochromatograph with dihydroxyeicosatetraenoic acid and monohydroxyeicosatetraenoic acid was seen; however, similar conversion was seen in bacteria-free control incubates. This implies that these compounds arise solely from autooxidation. The reduction in radioactivity corresponding to dihydroxyeicosatetraenoic acid and monohydroxyeicosatetraenoic acid in incubations containing bacteria when compared with controls was due to uptake of arachidonic acid into the bacteria, preventing its autooxidation. Radioactivity remaining within the organisms at the end of each experiment was measured to account for all of the radioactivity added at the start of each experiment. This excluded the possibility that the organisms are able to metabolize arachidonic acid to compounds that are not detectable with this system.

Our findings extend those of Gulbis et al.[10, 11] in demonstrating that common genital tract pathogens are unable to metabolize arachidonic acid to other eicosanoids by any of the established enzyme pathways. Arachidonic acid taken into bacterial cells may remain as a membrane component or be used as a source of energy. We have concluded that bacterial infection cannot initiate preterm labor in intrinsic biosynthesis and release of prostaglandins or other eicosanoids. Further work is needed to elucidate the precise mechanisms by which bacteria initiate preterm labor. It is likely, however, that a better understanding of the mechanisms of preterm labor will be gained by an increase in our understanding of the mechanisms of the onset of labor at term.

Renal autoregulation in midterm and late-pregnant rats

Jane F. Reckelhoff, PhD, Stanley D. Yokota, PhD, and Christine Baylis, PhD
Morgantown, West Virginia

OBJECTIVES: The normal kidney autoregulates (that is, maintains) renal blood flow over a wide range of arterial blood pressures. During normal pregnancy blood pressure falls and the kidney vasodilates. The purpose of this study was to investigate whether renal autoregulatory ability was influenced during pregnancy in the normal rat.
STUDY DESIGN: Experiments were conducted on three groups of anesthetized rats, studied in the virgin state, at midterm, and late in pregnancy (gestation lasts 22 days in the rat). Renal blood flow was measured by electromagnetic flow probe at normal renal perfusion pressures, during elevation in renal perfusion pressure with bilateral carotid occlusion, and at subnormal renal perfusion pressures after application of an aortic snare.
RESULTS: Blood pressure was similar in midterm and virgin rats but lower in late pregnancy in the control state. Control renal blood flow was similar between virgin and late-pregnant rats but significantly elevated at midterm. During elevation in blood pressure with bilateral carotid occlusion, autoregulation was maintained in all three groups. During graded aortic occlusion, renal autoregulatory ability was lost. The autoregulatory threshold was between 90 and 100 mm Hg for midterm pregnant and virgin rats and was slightly lower at about 88 mm Hg for late-pregnant rats.
CONCLUSIONS: Midterm pregnant rats are able to autoregulate renal blood flow as well as virgins are in spite of underlying gestational renal vasodilatation. The slight shift in renal autoregulatory threshold seen in late-pregnant rats may prevent the kidney from hypoperfusion during late-gestation hypotension. (Am J Obstet Gynecol 1992;166:1546-50.)

Key words: Renal blood flow, pregnancy, autoregulation, rat

In normal pregnancy in women early increases occur in glomerular filtration rate and renal blood flow that reach a maximum of approximately 50% above the nonpregnant value.[1] In addition, total peripheral resistance declines so that in spite of concomitant plasma volume expansion the mean arterial blood pressure decreases by midterm.[1] In the normotensive pregnant rat qualitatively similar changes occur, although the temporal sequence is slightly different because the maximum decrease in renal vascular resistance occurs by midterm, whereas the decrease in arterial blood pressure occurs close to term.[2]

In the nongravid state renal function is preserved in the face of a decrease in arterial blood pressure by autoregulation of renal blood flow (and glomerular filtration rate), an intrinsic renal regulatory mechanism that maintains a constant blood flow (and filtration rate) over a wide range of arterial blood pressure.[3] Falls in arterial blood pressure below the autoregulatory range will, however, lead to renal hypoperfusion and a decline in glomerular filtration rate. Furthermore, reduced renal autoregulatory ability is seen even above the normal threshold for autoregulation, when the ambient tone in the renal vasculature is reduced with some but not all vasodilators.[3, 4] Because normal pregnancy is associated with early reductions in renal vascular tone and later reductions in arterial blood pressure, the current study was performed to investigate whether renal autoregulatory ability is altered in the pregnant rat. Studies were performed in anesthetized, volume-replete rats in the virgin state, at midterm (day 12), when the renal vasculature shows the maximal vasodilation but arterial blood pressure is normal, and in late pregnancy (day 19 to 20), when the renal vascular resistance is close to normal but gestational hypotension is evident.

Methods

All experiments were performed with female Munich Wistar rats (aged 4 to 6 months) obtained from Simonsen, Gilroy, California. Rats were maintained on a 12-hour-light and 12-hour-dark cycle and had access to food (standard rat chow, containing ~24% protein and ~0.4% sodium) and tap water at will. Three groups were studied: midterm rats at day 12 of gestation, late-pregnant rats at days 19 to 20 of pregnancy (gestation lasts 22 days in the rat), and age-matched virgin females. Rats destined to become pregnant were placed together with a fertile male, and day 1 of pregnancy

was determined by the presence of sperm in the vaginal smears.

On the day of study rats were anesthetized by intraperitoneal injection of the long-acting thiobarbiturate Inactin (120 mg/kg body weight) (Byk Gulden Konstanz, Germany) and placed on a temperature-regulated surgery table; rectal temperature was maintained at 36° to 38° C. The left femoral artery was catheterized for periodic blood sampling and for monitoring arterial blood pressure (Gould P23 pressure transducer [Gould Inc., Oxnard, Calif.] connected to a Grass model 5D polygraph [Grass Instruments, Quincy, Mass.]) throughout the experiment. A femoral vein was also cannulated for infusion of isoncotic, artificial serum (2.5 gm/dl bovine serum albumin, 2.5 gm/dl bovine immunoglobulin in lactated Ringer's solution) at 12.5 ml/kg body weight per hour for 45 minutes during the preparatory surgery and thereafter at 1.5 ml/kg body weight per hour throughout the experiment. This protocol was effective in maintaining arterial hematocrit and plasma volume at preanesthesia levels during the preparatory surgery and throughout the experiment, thus preserving a euvolemic preparation.[5] Loose ligatures were placed around both carotid arteries, a tracheostomy was performed, and one jugular vein was catheterized for infusion of paraaminohippuric acid (0.5 gm/dl in 0.9% sodium chloride solution, 1 ml/hr). Midline abdominal and left subcostal incisions were made and a loose ligature was placed around the aorta above the level of both renal arteries. An electromagnetic flow probe (2 mm inner diameter, Carolina Medical Electronics, King, N.C.) was placed on the left renal artery, and renal blood flow was measured and recorded continuously (Grass model 5D polygraph). The left ureter was also cannulated for collection of urine during the control period only.

After a 60-minute equilibration period for paraaminohippuric acid infusion, a control period was performed during which an exactly timed (20-minute) urine sample was collected and a midpoint blood sample was drawn for measurement of renal blood flow (by paraaminohippuric acid clearance) to calibrate the flow probe. Renal blood flow was measured by electromagnetic flow probe only during the remainder of the experiment. After control, bilateral carotid occlusion increased arterial blood pressure, and renal blood flow and arterial blood pressure were measured during a 10- to 15-minute period. Although activation of efferent renal sympathetic nerve activity cannot be excluded, during carotid occlusion this most likely did not occur because the left kidney would be functionally denervated during dissection of the left renal artery and placement of the flow probe. Next, the ligatures around the carotid arteries were loosened and the ligature surrounding the aorta was tightened in a stepwise fashion to produce graded decreases in arterial blood pressure <90 mm Hg, in 10 mm Hg steps, down to 60 mm Hg. Each decrease in arterial blood pressure was followed by a 5-minute equilibration period and a 15- to 20-minute period during which renal blood flow and arterial blood pressure were measured.

At the termination of each experiment, zero blood flow was determined by occluding the renal artery on the side proximal to the kidney. Paraaminohippuric acid levels in urine and plasma samples during the control period were determined colorimetrically,[6] and clearance of paraaminohippuric acid was used to calculate renal plasma flow (and thus renal blood flow), assuming renal paraaminohippuric acid extraction to be 85%. The calculated renal blood flow (from paraaminohippuric acid clearance) obtained in the control period was then used to calibrate the flow probe. Before the study the flow probe was tested for linearity and stability with a dissected, suspended portion of the aorta and found to be linear in the range of 1 to 10 ml/min.

Autoregulatory curves of renal blood flow versus arterial blood pressure in control, with carotid occlusion and during graded aortic occlusions, were plotted for each animal. Values of renal blood flow at arterial blood pressures of exactly 80, 70, and 60 mm Hg were obtained by interpolation from individual animal autoregulatory curves. Statistical significance was determined by analysis of variance, and data are expressed as mean ± SE. In these experiments the West Virginia University guidelines for care and use of animals were followed.

Results

Body weight increases significantly during pregnancy, whereas kidney weights were the same in all three groups (Table I). Hematocrit fell progressively during pregnancy compared with the virgin values, reflecting the progressive gestational plasma volume expansion.[2] The uteri of all pregnant rats were inspected during the experiment and appeared normal for the stage of pregnancy.

During the control period there was no difference in arterial blood pressure between midterm and virgin rats, although a gestational renal vasodilation was evident with a renal blood flow approximately 20% greater in midterm rats (Fig. 1, $p < 0.05$). By late pregnancy significant falls had occurred in arterial blood pressure in spite of plasma volume expansion, which implies that total peripheral vascular resistance is markedly diminished close to term. In spite of the evidence for a peripheral vasodilation (i.e., fall in arterial blood pressure), renal vasodilation had abated by late in gestation and there was no difference in control renal blood flow between late-pregnant rats and virgin controls, (Fig. 1)

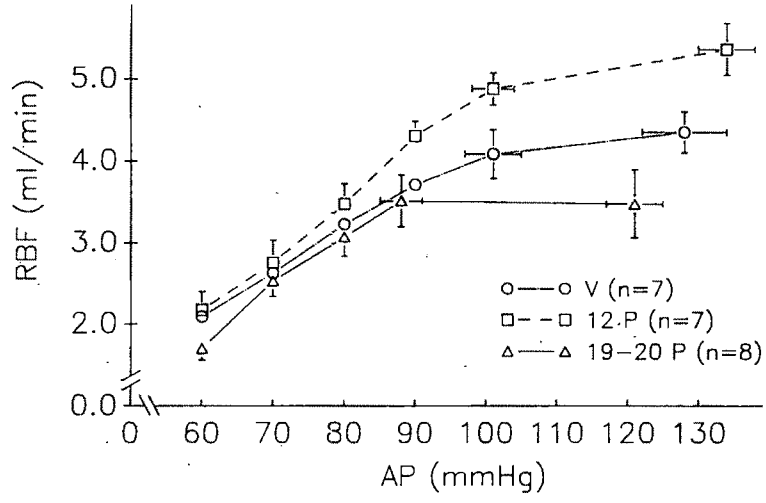

Fig. 1. Renal blood flow *(RBF)* at control blood pressure *(AP)*, at elevated arterial blood pressure during carotid occlusion and during reductions in arterial blood pressure by stepwise aortic occlusion in virgin (n = 7), midterm (12 days) (n = 7), and late-pregnant (19 to 20 days) (n = 8) rats. Mean ± SE for all renal blood flow measurements and for arterial blood pressure in control and during carotid occlusion. No standard errors are given for arterial blood pressure obtained during aortic occlusion because renal blood flow was determined at exactly 90 (virgins and midterm), 80, 70, and 60 mm Hg (all groups) by interpolation from individual animal autoregulatory curves.

Table I. Body weight, left kidney weight, and hematocrit in virgin (n = 7), midterm (n = 7), and late-pregnant (n = 8) Munich Wistar rats

Rats	*Body weight (gm)*	*Left kidney weight (gm)*	*Hematocrit (gm/dl)*
Virgins	202 ± 2	0.80 ± 0.01	47.5 ± 0.5
Midterm	236 ± 3*	0.85 ± 0.03	43.4 ± 0.6*
Late-pregnant	258 ± 4†‡	0.83 ± 0.03	40.6 ± 0.8†‡

All values are expressed as mean ± SE. Statistical significance was determined by analysis of variance.
*$p < 0.05$, midterm versus virgin rats.
†$p < 0.05$, late-pregnant versus virgin rats.
‡$p < 0.05$, midterm versus late-pregnant rats.

as previously reported for both the awake and anesthetized preparations.[7, 8] Renal blood flow was significantly lower in late-pregnant rats versus those in midpregnancy ($p < 0.01$).

Bilateral carotid occlusion produced ~30% increases in arterial blood pressure in all three groups (Fig. 1), and there was little effect on renal blood flow in virgin or pregnant rats. Thus differences in renal blood flow seen in control were maintained during carotid occlusion. During graded aortic occlusion reduction in arterial blood pressure to 90 mm Hg in virgins and midterm rats produced small decreases in renal blood flow (Fig. 1) of ~10% (Fig. 2). In late-pregnant rats control arterial blood pressure was ~90 mm Hg and control renal blood flow was similar to that in virgins and in midterm rats after arterial blood pressure reduction to 90 mm Hg. When arterial blood pressure was reduced <90 mm Hg, renal blood flow decreased in proportion to the decrease in arterial blood pressure in all three groups. There was no difference in renal blood flow among the groups at any arterial blood pressure.

Fig. 2 shows the percent change from control in renal blood flow (where control is 100%) during experimentally induced variations in arterial blood pressure. The inflection point of each curve represents the autoregulatory threshold, and, as shown, this threshold for virgin and midterm rats lies between 90 and 100 mm Hg. However, the autoregulatory threshold for late-pregnant rats is reset to a lower value of 88 mm Hg, which is the value of arterial blood pressure in control for these rats. In all groups autoregulation was in the arterial blood pressure range between control and bilateral carotid occlusion. At an arterial blood pressure between control and 90 mm Hg, there was impaired and variable autoregulation of renal blood flow in midterm rats, and renal autoregulation was absent in vir-

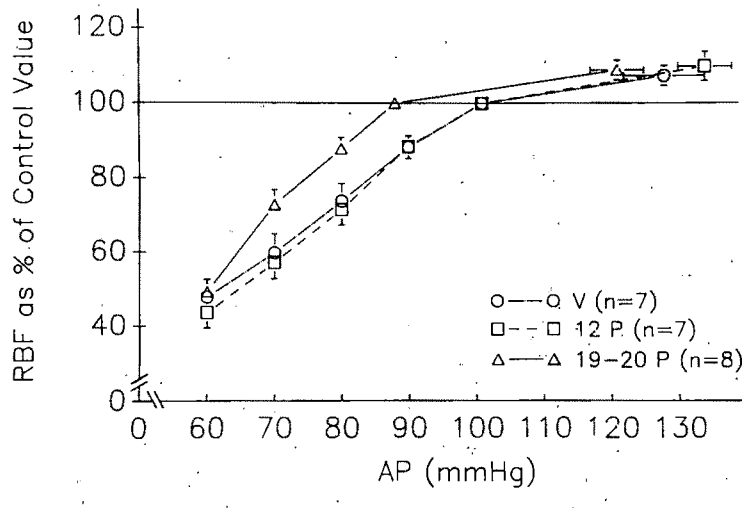

Fig. 2. Renal blood flow *(RBF)* during experimentally induced increases and decreases in arterial blood pressure *(AP)* expressed as percent of control renal blood flow. Data are given for virgins *(circles, dash-dot line)*, midterm *(squares, dashed line)*, and late-pregnant *(triangles, solid line)* rats.

gins. At values of arterial blood pressure <90 mm Hg, autoregulation was absent in all three groups (Fig. 2).

Comment

Several studies in nongravid animals have shown diminished autoregulation of renal blood flow during acute drug-induced systemic and renal vasodilatation.[4, 9] Selective renal vasodilation, by infusion of amino acids or hyperglycemia, also significantly impaired autoregulatory efficiency of renal blood flow.[10, 11] In pregnancy the kidney is chronically vasodilated, with glomerular filtration rate and renal blood flow reaching their gestational maximums early in pregnancy, and renal vasodilatation is sustained until near term, when glomerular filtration rate and renal blood flow return to prepregnant values.[1, 2] Our current study shows that, in contrast to the autoregulatory impairment seen with acute vasodilatation, with the chronic renal vasodilation of pregnancy there is apparently some resetting of the renal vasculature, so that an appropriate autoregulatory resistance change occurs in response to a change in pressure in spite of a chronic increase in vessel radius. In other words, the chronic gestational renal vasodilatation does not impair the autoregulatory ability of the kidney. Furthermore, in previous studies we have shown that the chronically vasodilated kidney of the midterm rat is also capable of responding with an appropriate acute renal vasodilatation in response to amino acid infusion.[12] One might expect that further vasodilatory responses would be attenuated in the already vasodilated renal vasculature of midterm pregnancy, but glycine infusion caused similar renal vasodilatation in both midterm and virgin rats.[12]

The results of our current study agree with a study by Woods et al.[13] in late-pregnant rabbits. These workers demonstrated similar autoregulation of renal blood flow and glomerular filtration rate between an arterial blood pressure of 70 and 100 mm Hg in virgins and in rabbits exhibiting a gestational renal vasodilatation in which renal blood flow was elevated by ~30%. However, one difference between their work and our study is that there was no gestational decrease in arterial blood pressure close to term in pregnant rabbits.[13] Studies by others in conscious, chronically catheterized rabbits disagree about whether rabbits demonstrate a late gestational hypotension,[13-15] and this variability probably depends on the time interval between catheterization and the experiment and the anxiety level of the rabbit during the experiment. By contrast, late pregnancy in rats is usually associated with gestational decreases in arterial blood pressure close to term regardless of whether the animals are studied under anesthesia or in the conscious, chronically catheterized preparation.[2, 7, 8] In our current study, by late pregnancy the gestational renal vasodilation has abated at a time when peripheral vasodilatation, plus opening of the uteroplacental shunt, had produced substantial falls in arterial blood pressure. Our findings indicate that the threshold for renal autoregulation changes close to term in pregnant rats and shifts to a slightly lower arterial blood pressure. If the autoregulatory threshold did not shift downward, the gestational decrease in arterial blood pressure would increase the risk of hypoperfusion of the maternal kidney. It is interesting that the arterial blood pressure of normal animals (whether pregnant or not) is close to the lower limit of autoregulation. Thus there is relatively little autoregulatory protection against renal hypoperfusion in the event of decreases in arterial blood pressure,

whereas autoregulatory mechanisms are most efficient at protecting the glomerulus from elevations in arterial blood pressure in the normal animal.

The current work does not address the mechanism(s) controlling renal autoregulation. It is currently believed that two major mechanisms control renal autoregulation, the myogenic and the tubuloglomerular mechanisms.[3] The myogenic theory states that changes in tone of the vascular smooth muscle of the afferent arteriole occur in response to changes in transmural pressure because of an inherent characteristic of the vessel. The tubuloglomerular feedback theory of autoregulation suggests that changing arterial blood pressure changes some signal that is sensed by the macula densa in the distal tubule, which in turn affects the resistance of the afferent arteriole of the same nephron. Woods et al.[13] believe that a tubuloglomerular feedback mechanism is responsible for renal autoregulation in pregnancy. Consistent with this hypothesis is our previous work in midterm rats in which we found that tubuloglomerular feedback activity is intact in spite of the gestational increase in plasma volume.[16]

In summary, we have found that autoregulation of renal blood flow is intact both in midterm rats when renal vasodilation is at its gestational maximum and arterial blood pressure is unchanged, and in late-pregnant rats when arterial blood pressure is decreased and renal vascular resistance is returning to the nonpregnant state. We have also shown that the autoregulatory threshold in late-pregnant rats is shifted toward lower arterial blood pressure, which may be a defense mechanism that helps prevent hypoperfusion of the maternal kidney when arterial blood pressure characteristically falls close to term.

We thank Lennie Samsell, Kevin Engels, and Paul Harton for excellent technical assistance.

Effects of antenatal thyrotropin-releasing hormone, antenatal corticosteroids, and postnatal ventilation on surfactant mobilization in premature rabbits

Steven Seidner, MD, Evelyn Rider, MD, Alan Jobe, MD, PhD, Takako Yamada, MD, and Machiko Ikegami, MD, PhD

Torrance, California

OBJECTIVE: The effects of antenatal hormones on postnatal surfactant mobilization were evaluated in preterm rabbits.

STUDY DESIGN: Pregnant rabbits were treated with vehicle, betamethasone, or thyrotropin-releasing hormone for 2 days before cesarean section at 29 days' gestation (term 31 days). Newborns were mechanically ventilated or allowed to spontaneously breathe, and groups were compared by analysis of variance.

RESULTS: Neither antenatal corticosteroids nor thyrotropin-releasing hormone increased radiolabeled precursor incorporation, alveolar wash or total lung saturated phosphatidylcholine pools, lung clearance of radiolabeled rabbit surfactant, or estimated net secretion of saturated phosphatidylcholine. However, saturated phosphatidylcholine pools in alveolar wash increased 2.7-fold during the first 24 hours in spontaneously breathing rabbits versus 2.1-fold in mechanically ventilated thyrotropin-releasing hormone–treated and control rabbits ($p < 0.05$). In addition, estimated net secretion of precursor-derived saturated phosphatidylcholine was 50% higher after 24 hours in spontaneously breathing rabbits.

CONCLUSION: Mechanical ventilation may have hindered the mobilization of surfactant saturated phosphatidylcholine pools to the alveolar space after birth in preterm rabbits, but maternal hormonal therapies did not appear to influence this adaptive process or change surfactant metabolism. (Am J Obstet Gynecol 1992;166:1551-9.)

Key words: Betamethasone, thyrotropin-releasing hormone, rabbits, lung development, pulmonary surfactant

Antenatal maternal administration of both corticosteroids and thyroid hormones may precociously induce lung maturation in preterm animals, as assessed by morphologic, physiologic, and biochemical criteria.[1, 2] Excellent reviews by Ballard[1] and Rooney[2] describe numerous studies in which both corticosteroids and thyroid hormones were associated with increased activities of the synthetic enzymes of surfactant saturated phosphatidylcholine in vitro, increased choline incorporation into saturated phosphatidylcholine in vitro, and increased lung lavage contents of saturated phosphatidylcholine in fetal rabbits before the onset of breathing. In contrast, when preterm rabbits at 27, 28, or 29 day's gestation were mechanically ventilated for 30 to 60 minutes before having their lungs lavaged, the saturated phosphatidylcholine pools recovered from the lavages were no longer increased after the antenatal administration of corticosteroids or thyrotropin-releasing hormone.[3-6] However, these apparently conflicting results would be compatible if the prenatal stimulation of synthesis or secretion after hormonal therapy was offset by an equivalent inhibition of secretion or increase in reuptake after birth and the onset of ventilation. The individual components of surfactant saturated phosphatidylcholine metabolism (secretion, reuptake, synthesis, and clearance) have not been previously studied postnatally in mechanically ventilated preterm animals after maternal corticosteroids or thyroid hormones are given antenatally.

For several reasons we chose to study preterm rabbits at 29 days' gestation whose mothers received hormonal therapy on the twenty-seventh and twenty-eighth days of gestation. First, the rates of surfactant secretion and recycling are very high in the lungs of preterm rabbits delivered at 29 days' gestation as demonstrated by the 30-fold increase that occurred in their alveolar phosphatidylcholine pools from delivery to 24 hours after the onset of spontaneous breathing.[7] Second, rabbits at this gestational age in our laboratory still had significant surfactant deficiency, with alveolar pool sizes of <10 μmol saturated phosphatidylcho-

line/kg body weight after 30 minutes of ventilation,[6] and a need for supplemental oxygen for survival (unpublished data). Third, we were able to maintain rabbits at this gestational age on mechanical ventilation for up to 24 hours, enabling randomization of large litters to various treatments at multiple time points. Finally, when preterm rabbits at various gestational ages received corticosteroids by maternal administration during the 2 days before delivery, the maximal effect on protein leak and lung function, in the absence of exogenous surfactant replacement, was seen when the mother was treated at 27 and 28 days' gestation and the fetuses were delivered at 29 days.[6]

Methods

Maternal corticosteroid and TRH treatment. Pregnant New Zealand White rabbits were injected with either saline vehicle or 0.1 mg/kg betamethasone (Celestone Soluspan, Schering, Kenilworth, N.J.) given intramuscularly 48 and 24 hours before delivery, or 0.02 mg/kg TRH (Bachem, Torrance, Calif.), given intravenously 48,36, 24, and 12 hours before delivery on the twenty-ninth gestational day. Vehicle control, corticosteroid-treated, and TRH-treated litters were studied on the same day. Vehicle control and TRH-treated litters were either allowed to spontaneously breathe or were tracheostomized and mechanically ventilated. All corticosteroid-treated litters were mechanically ventilated due to the lower birth weights and increased lability of the rabbits from those litters. Similarly, exclusion criteria were selected so that all the animals analyzed were in comparable pH balance (see Data analysis). All guidelines for the care and use of the rabbits approved by our institution were followed.

Radioisotope and surfactant preparation. Palmitic acid (1-carbon 14, 56 Ci/mol) and phosphorus 32 (carrier-free, as orthophosphate) were purchased from ICN Pharmaceuticals (Irvine, Calif.). The palmitic acid was converted to the sodium salt and stabilized with 6% bovine serum albumin.[8] These isotopes were then combined in a 0.9% sodium chloride solution containing 15 μCi/ml [^{14}C]palmitic acid and 80 μCi/ml [^{32}P]orthophosphate and kept frozen until use.

Unlabeled natural rabbit surfactant was prepared from the pooled lung lavages of adult rabbits, and the large surface-active aggregates were isolated by centrifugation of the alveolar wash at 8000 *g* for 30 minutes at 4° C over 0.7 mol/L sucrose.[9] The large aggregates recovered at the interface were pelleted at 40,000 *g* and resuspended in 0.9% sodium chloride solution for later use. The rabbit surfactant was then radiolabeled by mixing it with a suspension of liposomes made with [^{3}H]choline-labeled dipalmitoylphosphatidylcholine.[10] The mixture was centrifuged at 27,000 *g* for 15 minutes, and the pellet was suspended in 0.45% sodium chloride solution to obtain a final concentration of 1.3 μCi/ml and 1 mg dipalmitoylphosphatidylcholine/ml. Liposomes made in this manner and associated with natural-surfactant large aggregates were shown previously to have the same lung clearance kinetics as natural surfactant in 3-day-old rabbits.[10]

Delivery and ventilation. On the twenty-ninth day of gestation the does were anesthetized with intravenous pentobarbital and given supplemental oxygen by face mask. Local anesthesia with 1% lidocaine was given in the abdominal wall, followed by exposure of the uterus and sequential delivery of the rabbit fetuses. Each newborn was then weighed, and those that were tracheostomized and mechanically ventilated were given a mixture of 10 mg/kg ketamine and 0.1 mg/kg acepromazine intraperitoneally. Those newborns randomized to the mechanically ventilated groups were tracheostomized with a tube made from an 18-gauge needle and given 150 μl of the preparation of tritium-labeled rabbit surfactant. This low dose of surfactant was administered after lightly compressing the chest until tracheal fluid completely filled the endotracheal tube and was immediately followed by the administration of several breaths of 100% oxygen with an anesthesia bag. By 3 minutes of age each rabbit was transferred to a temperature-controlled ventilator-plethysmograph with each set of 10 ventilator circuits driven by a time-cycled, pressure-limited Sechrist infant ventilator (Sechrist Industries, Inc., Anaheim, Calif.).[4] Each rabbit was then continuously ventilated with 50% oxygen at a rate of 30 breaths/min with an inspiratory time of 0.7 seconds and no positive end-expiratory pressure. Peak inspiratory pressure was regulated individually every 20 to 30 minutes with a series of water columns to maintain the tidal volume at 12 ml/kg body weight, as measured with a pneumotachometer.[4] This amount of ventilation was found to result in stable compliances and normal P_{CO_2} values when the rabbits were killed. Dynamic compliance measurements were calculated by dividing tidal volume/kg body weight by peak inspiratory pressure. After delivery of the spontaneously breathing control and TRH-treated litters, the newborn rabbits were thoroughly dried, stimulated, and placed in an incubator at 37° C with 50% oxygen for 30 minutes before the intratracheal and intravenous injections of radioisotopes. After 30 minutes, the rabbits were injected intratracheally with 150 μl of the preparation of tritium-labeled rabbit surfactant with a 27-gauge needle.[11]

Each newborn rabbit was injected through the external jugular vein with 0.2 ml of the [^{14}C]palmitate and [^{32}P]orthophosphate surfactant precursor solution 10 minutes after receiving the intratracheal surfactant. Each rabbit was fed 20 to 30 minutes after birth and every 8 hours thereafter with 1 to 1.5 ml of Esbilac

Table I. Description of groups of animals

formula (Pet-Ag, Inc., Hampshire, Ill.) through a 3.5Fr orogastric infant feeding tube. This feeding schedule successfully prevented hypoglycemia as measured by Dextrostix on terminal blood samples. Oxacillin, 50 mg/kg, was given intramuscularly at 2 and 14 hours of life. Rabbits from each litter were killed with intrathecal injections of lidocaine at 1, 4, 8, 15, and 24 hours after receiving the intravenous doses of radiolabeled precursors, and terminal blood samples were drawn from the hearts for blood gas analysis.

Processing of lungs. The chest of each rabbit was opened and five aliquots of sufficient 0.9% sodium chloride solution to distend the lungs (2 to 3 ml) were flushed into and out of the airways three times for each aliquot and then pooled as the alveolar wash before storage at −20° C for further analysis. The postlavage lung tissue was then removed from the chest, weighed, and homogenized in 4 ml sodium chloride solution before storage at −20° C as the lung homogenate. Lipids from aliquots of the alveolar washes and lung homogenates and from duplicate samples of the intratracheal injection solutions were extracted with chloroform/methanol (2:1) and dried under nitrogen at 50° C.[12] The lipid extracts were then treated with osmium tetroxide and the saturated phosphatidylcholine was recovered from the extracts by column chromatography with neutral alumina according to Mason et al.[13] Each saturated phosphatidylcholine sample was then split and analyzed for phosphorus content according to Bartlett[14] and radioactivity by liquid scintillation counting with Aquasol II (New England Nuclear, Boston).

Data analysis. Rabbits were excluded from analysis for terminal pH values <7.00 or P_{CO_2} values >65 mm Hg. Results are reported as group means ± SEM unless otherwise indicated. The rates of clearance of the radiolabeled intratracheal surfactant preparations were calculated from the slopes of the linear regression curves of the recovery percentages. Differences between hormonal treatment groups were tested by analysis of variance followed by the Student–Newman-Keuls multiple comparison procedure. Differences between mechanically ventilated and spontaneously breathing rabbits for the TRH-treated and vehicle control litters were tested by two-way analysis of variance.

Results

Description of animals. Of the mechanically ventilated preterm rabbits, 77% of the control group, 72% of the TRH group, and 46% of the betamethasone group satisfied the pH and P_{CO_2} criteria and were included in the results. Metabolic acidosis and intravascular volume depletion by clinical assessment accounted for the vast majority of those excluded from analysis, regardless of the treatment group. The significantly higher exclusion rate in the newborns from the betamethasone group was probably a secondary effect of smaller intravascular volumes at birth after their intrauterine growth retardation. Of the spontaneously breathing rabbits, 96% of the control group and 86% of the TRH group met the inclusion criteria. The number of animals included in the results for each group and for body weights and mean tidal volumes during mechanical ventilation are shown in Table I. Maternal corticosteroid treatment resulted in a significant reduction in fetal body weight ($p < 0.05$), but peak pressures were adjusted accordingly so that mean tidal volumes were comparable in all the mechanically ventilated rabbits. The group means and SDs for pH and P_{CO_2} values obtained from the terminal blood gases from all the rabbits analyzed and for the mean peak inspiratory pressures and dynamic compliances of the mechanically ventilated rabbits analyzed are shown in Fig. 1. Neither antenatal maternal TRH nor betamethasone resulted in any significant differences in those animals that met the inclusion criteria. The dynamic compliances measured in the mechanically ventilated rabbits tended to improve with time. All rabbits initially had some degree of metabolic acidosis which seemed to improve over time and there was a somewhat higher

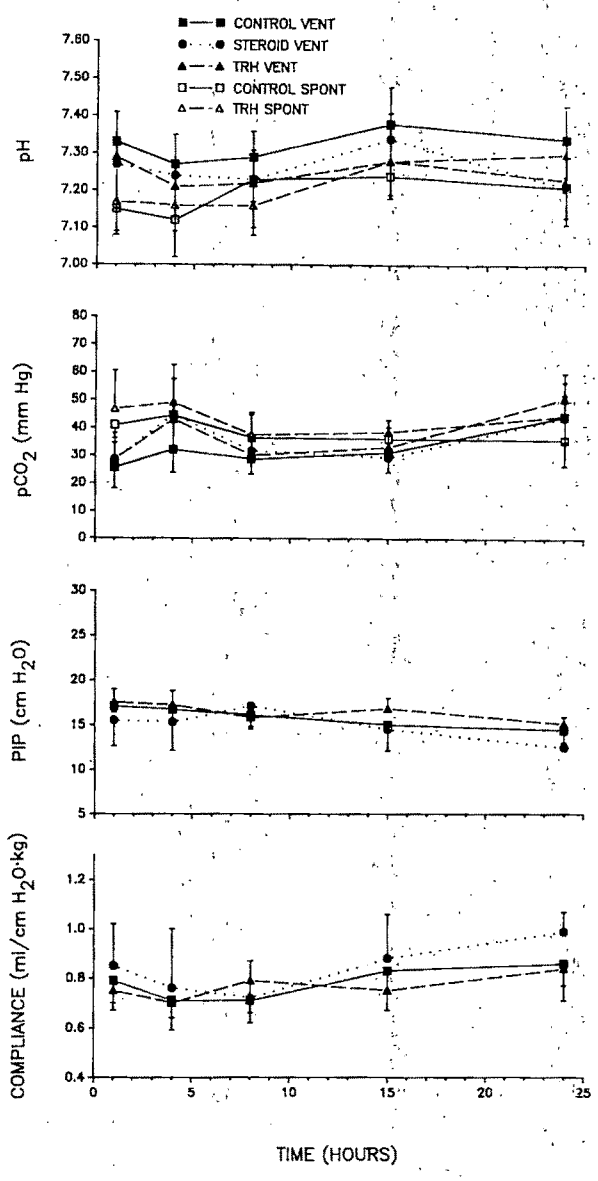

Fig. 1. pH, P_{CO_2}, peak inspiratory pressure *(PIP)*, and dynamic compliance values for those rabbits meeting inclusion criteria. Each point represents group mean ± SD for animals killed at that time. *Solid symbols*, Mechanically ventilated rabbits; *open symbols*, spontaneously breathing rabbits. Antenatal hormone treatments are represented by *different symbols* as indicated. Dynamic compliance and peak inspiratory pressure were only measured in mechanically ventilated rabbits.

degree of respiratory compensation after 1 hour in those rabbits that were mechanically ventilated.

Lung clearance of intratracheal saturated phosphatidylcholine liposomes associated with rabbit surfactant. Tritiated choline dipalmitoylphosphatidylcholine liposomes associated with natural rabbit surfactant were cleared from the total lungs (alveolar wash ± lung homogenate) of all groups at very slow rates of ≤1%/hour from 1 to 24 hours postnatally as calculated by linear regression of the total lung recovery curves (Table I). There were no significant differences resulting from either maternal hormone treatments or the use of mechanical ventilation.

Lung incorporation of saturated phosphatidylcholine precursors. ^{14}C-labeled palmitate was incorporated more rapidly and more efficiently into preterm rabbit lung saturated phosphatidylcholine (Fig. 2, *A*) than [^{32}P]orthophosphate, as expected (Fig. 2, *B*), because the former may enter the fatty-acid side chains of saturated phosphatidylcholine by remodeling or de novo synthesis whereas the latter must be incoprorated into the saturated phosphatidylcholine backbone by de novo synthesis. Because incorporation through the remodeling pathway is very rapid and probably more efficient than incorporation through de novo synthesis, the maximum incorporation for ^{14}C-labeled palmitate occurs by 1 hour, after which clearance of labeled saturated phosphatidylcholine equals or exceeds incorporation by de novo synthesis. However, the incorporation of the precursors was not significantly affected by maternal TRH, maternal betamethasone, or mechanical ventilation.

Estimated secretion of saturated phosphatidylcholine. Secretion of lung saturated phosphatidylcholine into the air spaces after birth was estimated by measuring the percentage of ^{14}C-precursor–labeled saturated phosphatidylcholine recovered from the alveolar wash relative to the recovery from the total lung (Fig. 3). As expected, the percentage of precursor-labeled saturated phosphatidylcholine recovered from the alveolar wash increased significantly over time in all groups. Neither maternal TRH nor corticosteroids caused any significant changes in the percentages of labeled saturated phosphatidylcholine recovered from the washes of the newborns at any of the time points studied. However, all groups of rabbits that were mechanically ventilated had significantly smaller percentages of precursor-labeled saturated phosphatidylcholine recoveries from their alveolar washes after 24 hours than did rabbits allowed to spontaneously breathe ($p < 0.05$).

Saturated phosphatidylcholine pool sizes. Saturated phosphatidylcholine pools recovered from the air spaces by alveolar wash and from the remaining lungs after homogenization increased significantly in all five groups from 1 to 24 hours ($p < 0.01$), but neither maternal TRH nor corticosteroid treatment resulted in significantly increased alveolar wash or lung homogenate saturated phosphatidylcholine pools compared with controls (Fig. 4, *A* and *B*). However, although neither lung homogenate (Fig. 3, *B*) nor total lung (alveolar wash + lung homogenates) saturated phosphatidylcholine pools (data not shown) were changed significantly by the mode of ventilation, the alveolar wash saturated phosphatidylcholine pools increased 2.1-fold postnatally from 1 to 24 hours in mechanically ventilated TRH and control groups compared with 2.7-fold in spontaneously breathing control and TRH groups

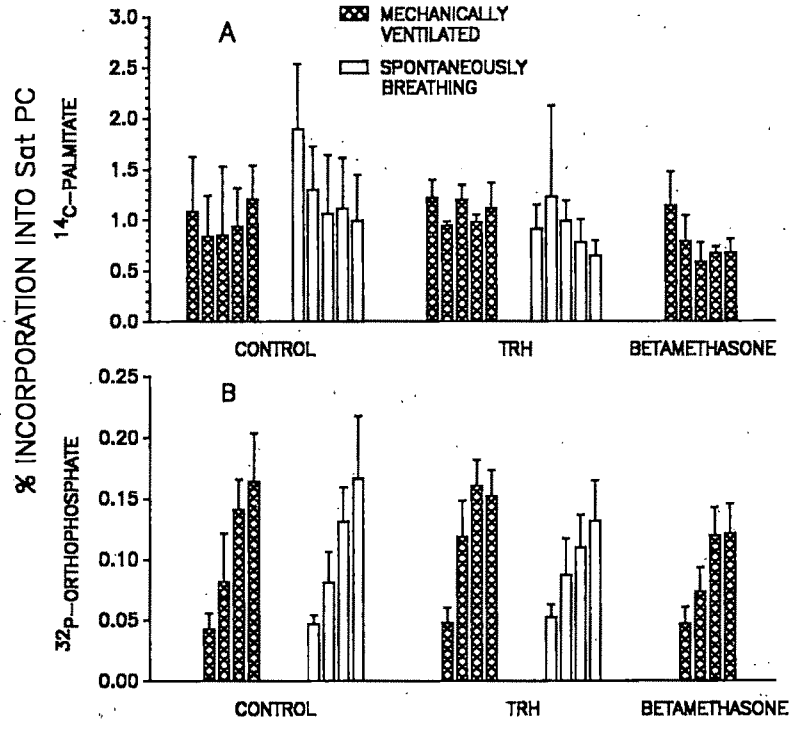

Fig. 2. Percentage of administered radiolabeled precursors incorporated into preterm rabbit lung saturated phosphatidylcholine *(Sat PC)* from 1 to 24 hours. All incorporation percentages refer to recoveries from total lungs (alveolar wash plus post lavage lung tissue). In **A** *bars* from left to right within each treatment group represent group means ± SE for rabbits killed at 1, 4, 8, 15, and 24 hours. Antenatal hormone treatments are indicated below *x* axis. *Cross-hatched bars,* Mechanically ventilated rabbits; *open bars,* spontaneously breathing rabbits. In **B** results are shown for rabbits killed at 4, 8, 15, and 24 hours because amount of ^{32}P incorporated by 1 hour was very low.

($p < 0.05$ by two-way analysis of variance), which was consistent with the lower estimated secretory rates and unchanged incorporation rates seen in those groups that were mechanically ventilated.

Lung uptake and recycling of surfactant saturated phosphatidylcholine. The fractional recovery from the alveolar wash of the tritiated saturated phosphatidylcholine that was given intratracheally after being associated with natural rabbit surfactant decreased initially consistent with reuptake but then actually had a tendency to increase during the later times, consistent with resecretion and increasing mobilization of alveolar pools (Fig. 5). This progression was not affected by maternal hormone treatments, but the spontaneously breathing controls and TRH-treated rabbits tended to have the largest increases in fractional recoveries from the alveolar washes at the later times.

Comment

Rooney et al.[15] found in preterm rabbits (27 days' gestation) that maternal TRH, at the same dose as in the current study (0.02 mg/kg for four doses), increased the alveolar pool sizes of phosphatidylcholine when lung lavages were performed before the onset of ventilation, whereas Ikegami et al.[5] found no significant change in alveolar pools compared with vehicle-injected controls when the lung lavages were done after 30 minutes of mechanical ventilation. Similarly, Fiascone et al.[3] recovered increased alveolar pools of surfactant phosphatidylcholine from unventilated preterm rabbit lungs after the administration of antenatal maternal corticosteroids when compared with the newborns of vehicle-injected controls but recovered much larger alveolar phosphatidylcholine pools with no differences between the offspring of corticosteroid-treated and controls after 1 hour of mechanical ventilation. However, an unchanged alveolar pool size may occur in spite of significant alterations in surfactant metabolism because synthesis, secretion, recycling, and clearance or degradation all contribute in a complicated manner to the resulting alveolar pools recovered.[16, 17] This is especially true near term during neonatal transition when both secretion into and reuptake from the alveolar space rapidly increase and then gradually reequilibrate to a new set point.[16] The alveolar pools of preterm rabbits at 29 days' gestation increased 30-fold from the time of delivery until 24 hours after the onset of spontaneous breathing,[7] and the alveolar pools of mechanically ventilated preterm lambs at 136 days' gestation increased fourfold from birth to 20 minutes of age and

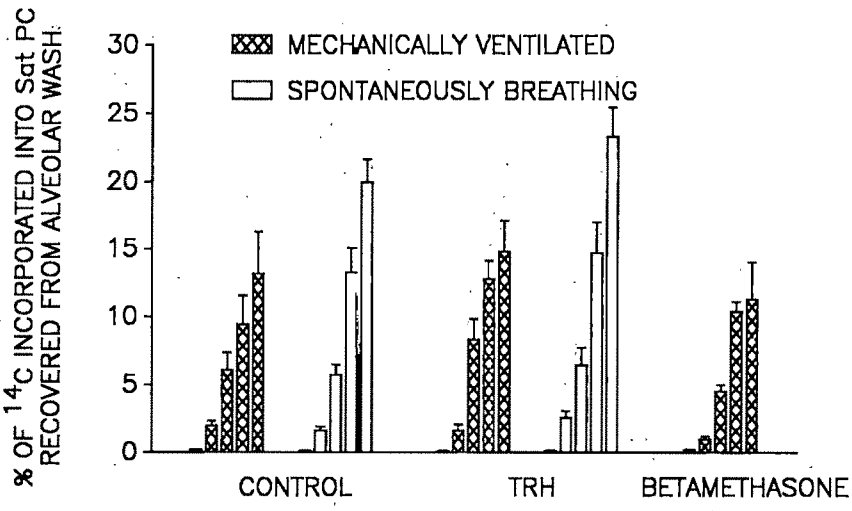

Fig. 3. Effects of various treatments on estimated net secretion of precursor-labeled saturated phosphatidylcholine *(Sat PC)* from 1 to 24 hours. Bars from left to right within each treatment group represent group means ± SE for rabbits killed at 1, 4, 8, 15, and 24 hours with almost no secretion seen in all groups at 1 hour. *Cross hatched bars,* Mechanically ventilated rabbits; *open bars,* spontaneously breathing rabbits. Antenatal maternal therapy is indicated below *x* axis under corresponding groups.

doubled again by 10 hours of age.[18] We studied preterm rabbits delivered at 29 days' gestation to measure the postnatal effects of hormonal agents and mechanical ventilation on surfactant saturated phosphatidylcholine metabolism during this period of rapid mobilization of surfactant saturated phosphatidylcholine pools into the air spaces.

Hormonal effects on lung maturation and surfactant metabolism are related to dose, species, the time in gestation during which they are administered, and whether they are given to the mother or the fetus.[19-25] Direct fetal administration of corticosteroids in lambs and rabbits appeared to cause more pronounced effects on surfactant phosphatidylcholine pools and smaller effects on overall fetal growth,[20,23-26] whereas maternally administered corticosteroids in rabbits and primates often did not cause any significant changes in phosphatidylcholine pool sizes in the fetuses but did inhibit growth in preterm rabbits.[4,5,19,23,27] Evaluating thyroid hormone effects on lung function and surfactant phospholipid metabolism is further complicated by interspecies differences in placental transport of thyroxine and triiodothyronine with particularly limited maternal-fetal transport across the human placenta. Thyroxine injected intraamniotically did appear to accelerate fetal lung maturation but required amniocentesis for administration.[28,29] TRH is clinically a potentially useful preparation because it readily crosses the human placenta and when given intravenously to mothers with term fetuses caused significant increases in cord blood levels of thyroid-stimulating hormone, triiodothyronine, and thyroxine 2 hours later.[30,31] The elevation of triiodothyronine and thyroxine in fetal blood was transient and was not seen 12 hours after maternal TRH administration in preterm rabbits[5] or humans.[30] Liggins et al.[32] found significant increases in alveolar pool sizes of saturated phosphatidylcholine at birth in preterm lambs given fetal infusions of TRH alone compared with controls and those given cortisol alone, which were not different from each other. Oulton et al.[24] found no significant increases in the alveolar phospholipid pools of 27-day preterm rabbits at birth after 0.04 mg/kg per dose of maternal TRH given intravenously in single or multiple doses (24 hours apart) from 24 to 26 days' gestation. However, the preterm rabbits all had increased lamellar body (intracellular) fractions of phospholipids compared with controls whose mothers did not receive TRH antenatally. These increased lamellar body pools would theoretically create a larger pool from which saturated phosphatidylcholine could be mobilized during neonatal transition, but increased mobilization after maternal TRH administration was not seen in 27-day preterm rabbits after 30 minutes of ventilation[5] in spite of larger alveolar pools seen at 27 days before the onset of ventilation.[15] This suggested to us that antenatal thyroid hormones might also have effects on postnatal secretion and recycling and that 29 days' gestation was a good time to study these phenomena because of the very high rate of mobilization previously seen at this point of development in spontaneously breathing rabbits.[7]

Maternal TRH administration might also stimulate lung maturation by increasing the release of prolactin or by direct central effects on respiratory timing because it has been shown to increase fetal breathing movements in lambs in utero[33] and to increase respiratory rate and minute ventilation in preterm rabbits spontaneously breathing at 29 days' gestation.[34] We

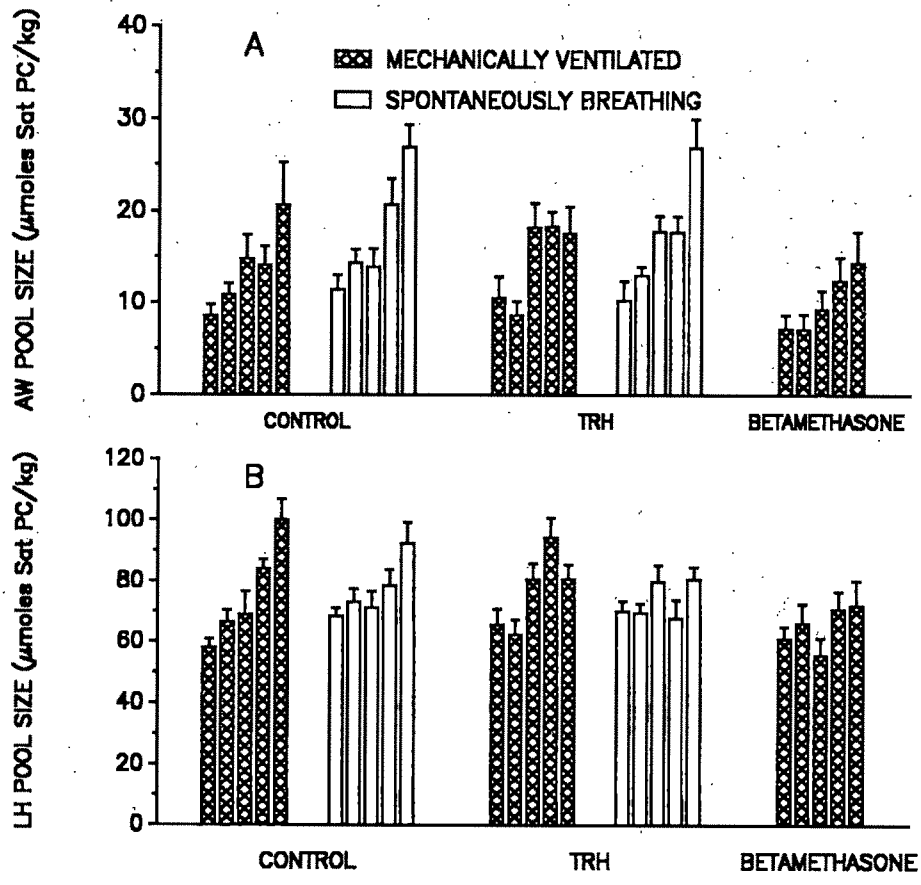

Fig. 4. Surfactant saturated phosphatidylcholine *(Sat PC)* pool sizes recovered from air spaces by alveolar wash *(AW)* in **A** and from remaining lung homogenates *(LH)* in **B** as determined by measuring total phosphorus content of saturated phosphatidylcholine fraction. Bars from left to right within each treatment group represent group means ± SE for rabbits killed at 1, 4, 8, 15, and 24 hours. Group means are expressed as micromoles saturated phosphatidylcholine per kilogram of body weight. Ventilatory style and antenatal hormonal therapy are as in previous figures. Proportion of total lung saturated phosphatidylcholine pool (alveolar wash plus lung homogenates) that was recovered from alveolar wash increased significantly over time in all groups ($p < 0.01$).

therefore studied the effects of matenal TRH on both mechanically ventilated and spontaneously breathing preterm rabbits and compared them with similarly ventilated controls. Because respiratory timing effects have not been reported after corticosteroid treatments and the newborns were smaller and generally more labile, we only studied mechanically ventilated rabbits for that treatment. However, in this study antenatal maternal TRH did not appear to affect surfactant saturated phosphatidylcholine metabolism in either spontaneously breathing or mechanically ventilated rabbits. Most of the previous studies had used much higher doses of TRH by direct fetal injection either intracerebrally or intravenously.[33, 34]

Total lung incorporation of radiolabeled palmitate and orthophosphate precursors into saturated phosphatidylcholine was not consistently affected by either hormonal treatments nor ventilatory style. Although it is possible that concurrent changes in precursor pool sizes of fatty acids and phosphate could have obscured any hormonal effects, it is unlikely that this occurred because the incorporation changed with time in a consistent and appropriate manner for two different precursors entering different pools. In addition, total lung saturated phosphatidylcholine pool sizes per kilogram body weight were also similar after TRH, corticosteroid, or vehicle administration. This strongly supports the existence of similar synthetic rates for saturated phosphatidylcholine because the contribution of lung clearance to the pool sizes was minor with <1% per hour cleared from the lungs in all the groups. The relatively small changes that occurred in parenchymal lung pools of saturated phosphatidylcholine after birth resulting from relatively little saturated phosphatidylcholine synthesis and very little clearance were consistent with the stable parenchymal saturated phosphatidylcholine lung pools and biologic half-lives of 100 to 360 hours for parenchymal saturated phosphatidylcholine estimated previously in 29-day spontaneously breathing rabbits in the newborn period.[7] Therefore

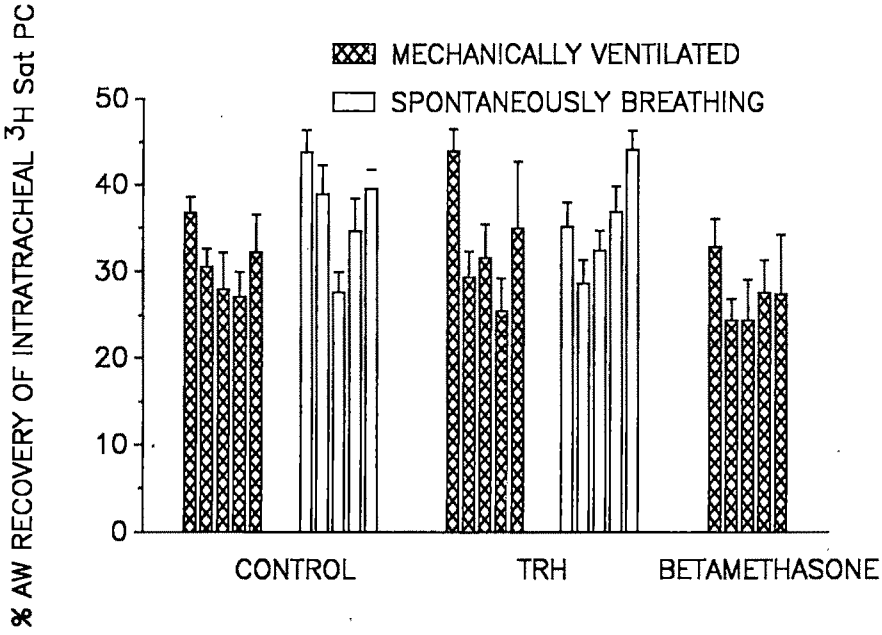

Fig. 5. Alveolar wash *(AW)* recovery of tritium-labeled rabbit surfactant given intratracheally at birth. These recoveries, expressed as percentages of radioactivity administered at birth, resulted from combined effects of surfactant saturated phosphatidylcholine *(Sat PC)* clearance, lung uptake, and resecretion into lungs. Rapid mobilization and resecretion of saturated phosphatidylcholine pools from lung parenchyma appeared to be more rapid than combined rates of lung uptake and alveolar degradation at the later time points. *Bars* from left to right within each treatment group again represent group means ± SE for rabbits killed at 1, 4, 8, 15 and 24 hours.

the large increases seen postnatally in saturated phosphatidylcholine alveolar pools after the onset of ventilation were much more dependent on changes in secretion and recycling resulting in mobilization of existing pools in the lung. Neither mechanical ventilation nor maternal hormonal treatments with TRH or corticosteroids resulted in decreasing the relative importance of mobilizing existing pools.

Because there was very little degradation of saturated phosphatidylcholine after birth, we were able to estimate net secretion into the air spaces by measuring the percentages of ^{14}C and ^{32}P incorporated from precursors into saturated phosphatidylcholine that were subsequently recovered from the alveolar washes. Assuming a totally efficient alveolar wash and negligible degradation, the net secretion would be equal to the total amount of radiolabel secreted into the air spaces minus the total amount reassociated with the lung. The percentages of precursor-labeled saturated phosphatidylcholine recovered from the alveolar washes would be directly proportional to the net secretion, assuming that the fractions of saturated phosphatidylcholine in the lung that were not part of surfactant pools remained constant. This assumption appeared to be valid because we saw no effects of antenatal maternal treatments with TRH or corticosteroids on either the pool sizes of saturated phosphatidylcholine recovered from the alveolar space or the estimated net secretion into the alveolar space. Although this study was designed primarily to examine the effects of antenatal maternal treatments with TRH or corticosteroids, the most intriguing differences were between those rabbits allowed to spontaneously breathe and those that were mechanically ventilated whether receiving antenatal TRH or vehicle. Preterm rabbits allowed to spontaneously breathe had significantly higher net secretions of saturated phosphatidylcholine at 15 and 24 hours compared with those that were mechanically ventilated. Spontaneously breathing newborns also had larger increases in their alveolar pools at 24 hours compared with those mechanically ventilated, also consistent with higher net secretions of saturated phosphatidylcholine because clearance and synthesis were not altered by the ventilatory style. Mechanically ventilated rabbits were given the same amount of oxygen, antibiotics, and nutrition as the preterm rabbits allowed to spontaneously breathe; there were no significant differences in the blood gases for those in which the higher net secretions were seen at 15 and 24 hours. We could not separate the effects of anesthesia and tracheostomy from those of mechanical ventilation in this study, but the slowing of net secretion appeared to be a secondary effect of lung injury or other changes that occurred in the lung after more prolonged ventilation because there were no differences seen at the earlier time points.

In summary, this was the first study where preterm

rabbits have been mechanically ventilated for up to 24 hours, and the majority tolerated the procedure well as assessed by terminal blood gas analysis. The 24-hour postnatal course of the preterm rabbit at 29 days' gestation provided a unique opportunity to observe a period of extremely rapid mobilization of lung-associated surfactant saturated phosphatidylcholine into the alveolar space. Even tritium-labeled surfactant saturated phosphatidylcholine given intratracheally failed to continuously decrease in the alveolar space with time (with a tendency to actually increase from 8 to 24 hours), suggesting that recycling and resecretion became as fast or faster than uptake by the lung. Antenatal maternal TRH or betamethasone in doses that improved lung function in 27 to 29-day preterm rabbits did not affect saturated phosphatidylcholine synthesis, clearance, or net secretion postnatally at 29 days' gestation. Mechanical ventilation was associated with a slower mobilization of lung-associated saturated phosphatidylcholine stores into the alveolar space after birth. Our results suggest that the ventilated preterm rabbit model may also be useful for studying relationships between mechanical ventilation and lung injury.

Nω-Nitro-L-arginine, an inhibitor of nitric oxide synthesis, increases blood pressure in rats and reverses the pregnancy-induced refractoriness to vasopressor agents

Miklós Molnár, MD, and Frank Hertelendy, PhD, DSc
St. Louis, Missouri

OBJECTIVE: With Nω-nitro-L-arginine, a potent inhibitor of nitric oxide synthesis, we tested the hypothesis that nitric oxide plays a functional role in the blunted pressor responsiveness seen during pregnancy.
STUDY DESIGN: A group of six pregnant rats were instrumented on the fourteenth day of gestation and studied on days 19 and 20, as well as 7 days post partum. Another group of six virgin rats were similarly prepared and used 5 days after surgery. Blood pressure and heart rate were monitored in conscious freely moving animals before and during the administration of drugs or placebo. Results were analyzed, by one-way repeated-measures analysis of variance, with Dunnett's *t* test, or by paired *t* test where applicable.
RESULTS: Basal mean arterial pressure and heart rate were 90.8 ± 3.0 mm Hg and 330 ± 6 beats/min in pregnant animals and 107.1 ± 3.2 mm Hg and 315 ± 7 beats/min in nonpregnant animals. Pressor responses to angiotensin II, vasopressin, and norepinephrine were attenuated in gravid animals. Infusion of Nω-nitro-L-arginine significantly and in a dose-dependent manner increased mean arterial pressure and reduced heart rate. These effects could be completely reversed by L-arginine administration. Changes in mean arterial pressure were higher during pregnancy as compared with postpartum values. Nω-nitro-L-arginine infusion potentiated pressor responses to all three vasopressors, resulting in dose-response curves that were significantly shifted to the left, making them virtually identical in pregnant and postpartum rats.
CONCLUSION: Our data support the emerging view that nitric oxide plays a key role in the regulation of blood pressure during pregnancy. (Am J Obstet Gynecol 1992;166:1560-7.)

Key words: Rat, pregnancy, nitric oxide, Nω-nitro-L-arginine, pressor responsiveness

Attenuated responses to vasopressor agents and reduced peripheral resistance and blood pressure are among the hemodynamic changes that characterize pregnancy. The mechanism(s) responsible for these phenomena is not known. Possible changes in affinity and/or density of vasoconstrictor receptors as causative factors have been ruled out.[1,2] In early studies inhibitors of cyclooxygenase (the enzyme responsible for the conversion of arachidonic acid to prostanoids) reduced the dose of vasopressors required to raise blood pressure in pregnant women; therefore it was proposed that vasodilator prostaglandins are responsible for the pregnancy-associated circulatory changes.[2-4] However, subsequent studies in the rat and guinea pig failed to corroborate these observations,[5,6] and the prostaglandin theory remains controversial. There is growing evidence that endothelium-derived factors may play important, local paracrine functions in the regulation of vascular tone.[7] We[8] have reported recently that, whereas pressor responses to angiotensin II and vasopressin were typically attenuated in chronically instrumented, conscious pregnant rats, the endothelin ET-1, a highly potent endothelium-derived vasopressor peptide, was equally effective in raising mean arterial pressure (MAP) in both pregnant and nonpregnant animals. Endothelium-derived relaxing factor, which is identical in its action to nitric oxide,[9] is synthesized by endothelial cells from the guanidino group of L-arginine.[10] Moreover, certain analogs of arginine, such as N-monomethyl-L-arginine and Nω-nitro-L-arginine, have been found to inhibit nitric oxide synthesis and vasodilatation in vitro,[11,12] as well as raise blood pressure in vivo.[11,13] We made use of the latter inhibitor, which has been reported to be significantly more potent than N-monomethyl-L-arginine,[11,12] to examine the possible role of endothelium-derived relaxing factor–nitric oxide in pregnancy-attenuated basal MAP and MAP responses to angiotensin II, vasopressin, and norepinephrine in chronically instrumented rats during preg-

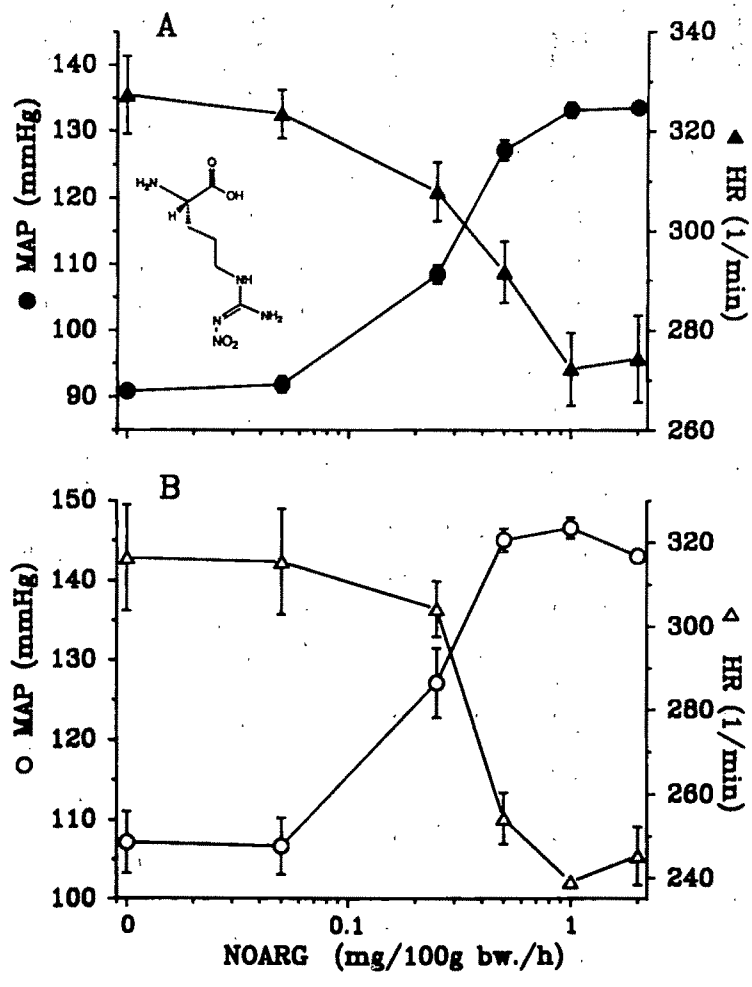

Fig. 1. Effect of infusion of Nω-nitro-L-arginine *(NOARG)* on MAP and heart rate in pregnant **(A)** and virgin **(B)** rats. *Inset,* Molecular structure of Nω-nitro-L-arginine. Experimental conditions are detailed in Material and Methods section.

nancy and 7 days post partum. Our results support the notion that blunted pressor responsiveness during normal gestation is due largely to increased elaboration of endothelium-derived–nitric oxide.

Material and methods

Reagents. Synthetic angiotensin II was purchased from Calbiochem (La Jolla, Calif.). Nω-nitro-L-arginine methyl ester, arginine vasopressin, norepinephrine, and all other chemicals used were obtained from Sigma Chemical Co. (St. Louis).

Preparation of chronically catheterized rats. Wistar-derived pregnant rats (LATI, Gödöllö, Hungary) weighing 260 to 300 gm were kept in standard metabolic cages for 3 days before surgery. The guidelines approved by the animal research committee of Semmelweis Medical University for the care and use of animals were followed throughout this study. Animals were instrumented while they were under surgical level anesthesia on the fourteenth day of gestation (delivery on day 21 or 22) according to Fejes-Tóth et al.[14] In brief, with the animals under ketamine (75 mg/kg body weight) and pentobarbital (15 mg/kg body weight) anesthesia, polyethylene catheters (PE-10, Clay Adams, Parsippany, N.J.) were implanted into the abdominal aorta and vena cava through the ventral tail artery and femoral vein, respectively. The venous catheter was guided subcutaneously to the root of the tail. Both catheters emerging from the tail and the wounds were protected by an acrylic cuff glued to the tail. The cuff was connected to a stainless steel helical spring leading through the top of the metabolic cage, allowing easy hookup to recorder and infusion pump.

Measurement of MAP and pressor responsiveness. On day 19 sterile saline solution was infused at 0.5 ml/100 gm body weight per hour via the venous catheter, and MAP was recorded in conscious, freely moving rats by means of an electromanometer (Medicor, Budapest) and a Statham P23dP pressure transducer (Hato Rey, Puerto Rico). After an equilibration period

Table I. Effect of infusion of L-arginine and combined infusion of L-arginine with Nω-nitro-L-arginine on angiotensin II–, vasopressin-, and norepinephrine-induced pressor responsiveness in virgin and pregnant rats

	L-Arginine (5 mg/100 gm body weight/hr)			
Group	*Saline solution*	*Angiotensin II*	*Vasopressin*	*Norepinephrine*
Virgin MAP (mm Hg)	110.0 ± 4.1	144.3 ± 2.9	140.1 ± 2.5	146.5 ± 2.5
Pregnant MAP (mm Hg)	92.3 ± 3.9	115.8 ± 2.1	107.8 ± 4.5	110.3 ± 3.4

Chronically instrumented rats were infused at 0.5 ml/100 gm body weight via venous catheter with L-arginine (5 mg/100 gm body weight) or with L-arginine (5 mg/100 gm body weight) + Nω-nitro-L-arginine (1 mg/100 gm body weight) simultaneously. After an equilibration period of 1 hour, a single dose of angiotensin II (10 pmol/100 gm body weight), vasopressin (7 pmol/100 gm body weight), or norepinephrine (60 pmol/100 gm body weight) was injected into the vena cava and changes in MAP were monitored continuously as described in Material and Methods.

of 2 hours, each animal received increasing doses of angiotensin II in a volume of 5 μl/100 gm body weight, via the catheter implanted into the vena cava, followed by an injection of 100 μl of saline solution. A period of 20 minutes was allowed to elapse between the administration of incremental doses. The same procedure was repeated with vasopressin and norepinephrine. The next day Nω-nitro-L-arginine, dissolved in sterile saline solution, was infused at 1 mg/100 gm body weight per hour in a volume of 0.5 ml/hr, and MAP and pressor responses to angiotensin II, vasopressin, and norepinephrine were recorded as on the previous day. Pups were removed immediately after delivery, and the experiments were repeated on the same animals 7 days post partum or on weight- and age-matched virgin rats.

Measurement of effects of Nω-nitro-L-arginine in pregnant and virgin rats. Day 14 pregnant rats ($n = 6$) and weight- and time-matched virgin rats ($n = 6$) were instrumented and kept as described. Five days later sterile saline solution was infused at 0.5 ml/100 gm body weight via venous catheter. After an equilibration period of 1 hour increasing doses of Nω-nitro-L-arginine (0.05 to 2 mg/100 gm body weight) were infused for 1 hour at a rate of 0.5 ml/hr, and MAP and heart rate were recorded continuously in conscious, freely moving animals.

Statistical analysis. Pressor responses are expressed as MAP changes from preinfusion baseline (mean ± SEM). Statistical evaluation of dose-response values was done by one-way repeated-measures analysis of variance and Dunnett's t test. Comparisons of saline solution and Nω-nitro-L-arginine treatment and of pregnancy and postpartum values were done by paired t test.

Results

Basal MAP was significantly higher ($p < 0.005$) in nonpregnant animals (107.1 ± 3.2 mm Hg) as compared with pregnant values (90.8 ± 3.0 mm Hg). Infusion of Nω-nitro-L-arginine significantly and in a dose-dependent manner increased MAP and reduced heart rate in both pregnant and virgin animals, with an identical median effective dose of 0.25 ± 0.01 mg/100 gm body weight (Fig. 1). The maximal MAP responses were higher, though not significantly so ($p = 0.091$), in pregnant animals (42.7 ± 1.04 mm Hg) as compared with virgin animals (36.0 ± 3.6 mm Hg). Changes in heart rate were higher, but again not significantly so ($p = 0.093$), in virgin rats (77.3 ± 13.5 × 1/min) versus pregnant rats (55.0 ± 4.7 × 1/min). However, when Nω-nitro-L-arginine (1 mg/100 gm body weight per hour)–induced increments in MAP in late-pregnant animals (44.0 ± 3.4 mm Hg) were compared with those obtained in the same rats 7 days post partum (33.8 ± 7.6 mm Hg), these were found to be significantly different ($p < 0.005$ by paired t test). Nevertheless, MAP remained significantly ($p < 0.01$) higher in nonpregnant animals during the Nω-nitro-L-arginine infusion (Fig. 2). Infusion of a fivefold excess of L-arginine completely reversed Nω-nitro-L-arginine–induced pressor effects and reflex bradycardia (Fig. 3). Administration of L-arginine alone did not alter MAP in saline solution–treated rats and did not reduce the pressor responsiveness of angiotensin II, vasopressin, or norepinephrine. In animals pretreated with L-arginine (5 mg/100 gm body weight per hour), Nω-nitro-L-arginine (1 mg/100 gm body weight per hour) did not influence MAP or heart rate and did not affect angiotensin II-, vasopressin-, and norepinephrine-induced pressor responses (Table I).

Angiotensin II, vasopressin, and norepinephrine caused a dose-dependent rise in MAP. Dose-response curves for all agonists were shifted significantly to the right in pregnant animals (Figs. 4, 5, and 6). Angiotensin II and vasopressin were more potent vaso-

L-Arginine (5 mg/100 gm body weight/hr) plus Nω-nitro-L-arginine (1 mg/100 gm body weight/hr)			
Saline solution	*Angiotensin II*	*Vasopressin*	*Norepinephrine*
108.9 ± 3.9	140.3 ± 3.5	139.9 ± 4.4	142.7 ± 3.9
91.2 ± 4.1	120.0 ± 6.7	110.1 ± 3.6	95.3 ± 5.4

constrictors than norepinephrine. The angiotensin II–generated response curve yielded median effective dose values of 6.7 ± 0.69 and 12.5 ± 2.29 pmol/100 gm body weight for the nonpregnant and pregnant animals, respectively. The corresponding median effective dose values were 5.6 ± 1.79 and 10.2 ± 2.10 pmol/100 gm body weight for vasopressin and 43.4 ± 4.91 and 105.9 ± 8.41 pmol/100 gm body weight for norepinephrine. The maximal changes in MAP evoked by all three agonists were not significantly different. Infusion of Nω-nitro-L-arginine potentiated pressor responses to the pressor agent, resulting in dose-response curves that were significantly shifted to the left. Importantly, Nω-nitro-L-arginine reversed the blunted pressor responses to all agonists obtained during gestation, yielding dose-response curves that were virtually identical to those generated in nonpregnant rats (Figs. 4, 5, and 6). Median effective dose values for angiotensin II, vasopressin, and norepinephrine were reduced to 1.0 ± 0.18, 3.1 ± 1.08, and 17.3 ± 5.17 pmol/100 gm body weight, respectively. However, the maximal changes of MAP were not significantly different in either Nω-nitro-L-arginine or control (saline solution–treated) groups. The dose-response curves of all agonists used in this study were superimposable in virgin rats and in rats 7 days post partum (data not shown).

Comment

In the current study with chronically instrumented conscious rats, we have been able to show that intravenous infusion of Nω-nitro-L-arginine, a potent inhibitor of nitric oxide synthesis,[11, 12] causes a significant increase in basal MAP in nonpregnant rats but particularly in gravid rats. More importantly, during continuous infusion of Nω-nitro-L-arginine, the blunted vasopressor response to several agonists, which is characteristic of human and rodent pregnancy,[15-17] was obliterated.

Endothelium-derived relaxing factor is believed to be either identical or very similar to nitric oxide, and it contains a reactive nitrogen moiety synthesized from L-arginine as an endogenous substrate in vascular endothelium and in other cells.[10, 18, 19] Structural analogs of L-arginine, such as Nω-nitro-L-arginine or N-monomethyl-L-arginine, competitively inhibit the formation of nitric oxide, which can be reversed by excess amounts of L-arginine.[20] Indeed, the current study has demonstrated that in the presence of a continuous infusion of a fivefold excess of L-arginine, Nω-nitro-L-arginine had no influence on basal blood pressure or on the pressor effects of angiotensin II, vasopressin, or norepinephrine, providing strong evidence that its action is due specifically to the inhibition of nitric oxide synthesis from L-arginine. Additional evidence that the effect of L-arginine is specific was obtained by showing that the basal blood pressure and the pressor responses to angiotensin II, vasopressin, and norepinephrine were not affected by L-arginine treatment alone.

Normal human pregnancy is accompanied by striking cardiovascular changes. There is an increase in heart rate, cardiac output, and blood volume and a decrease in arterial pressure and responsiveness to angiotensin II.[16] The chronically instrumented conscious rat has been shown to exhibit gestation-induced cardiovascular and renal changes very similar to those observed in normal pregnant women,[5, 21] rendering it an appropriate and useful model for the investigation of pregnancy-induced hemodynamic changes, including the attenuated responsiveness to pressor agents.[22] These changes have been attributed to increased production of vasodilator prostanoids.[2-4] However, this concept has been disputed since inhibitors of cyclooxygenase failed to alter pressor responsiveness in the rat[5] and guinea pig.[6] There is growing evidence that substances derived from the endothelium may play crucial roles in the local paracrine regulation of blood pressure. Supporting the role of endothelium-derived relaxing factor in blood pressure regulation in the gravid female are the findings of an increased relaxant effect of acetylcholine in vascular preparations with intact endothelium of pregnant guinea pig,[23] as well as the significant increase during gestation in plasma and urinary levels of cyclic guanosine monophosphate,[24] be-

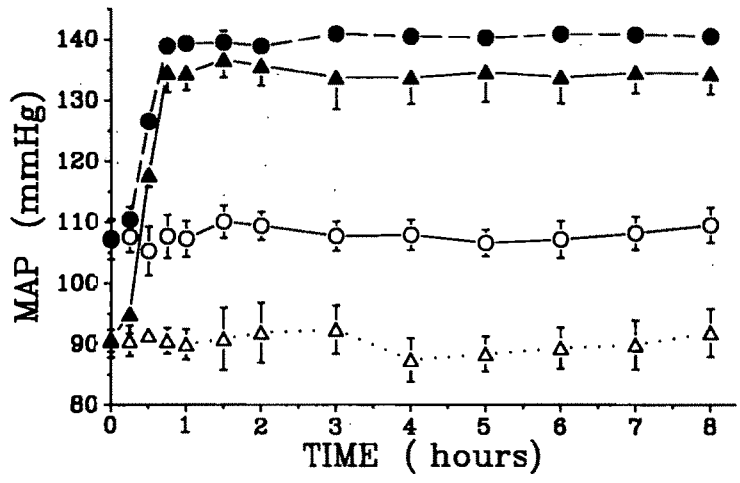

Fig. 2. MAP changes during infusion of Nω-nitro-L-arginine at rate of 1 mg/100 gm body weight per hour and saline solution, both at rate of 0.5 ml/hr, in chronically instrumented, conscious, pregnant and nonpregnant rats. Saline solution and Nω-nitro-L-arginine infusions were started at time 0. Values are mean ± SEM ($n = 6$). *Open symbols,* MAP measured during saline solution infusion in rats during pregnancy (△) and 7 days post partum (○). Every *point* of nonpregnant animals is significantly ($p < 0.005$) higher than corresponding pregnant values. *Closed symbols,* MAP values obtained during Nω-nitro-L-arginine infusion in pregnant (▲) and nonpregnant (●) animals. MAP of Nω-nitro-L-arginine–infused nonpregnant rats is significantly ($p < 0.05$) higher than corresponding pregnant values.

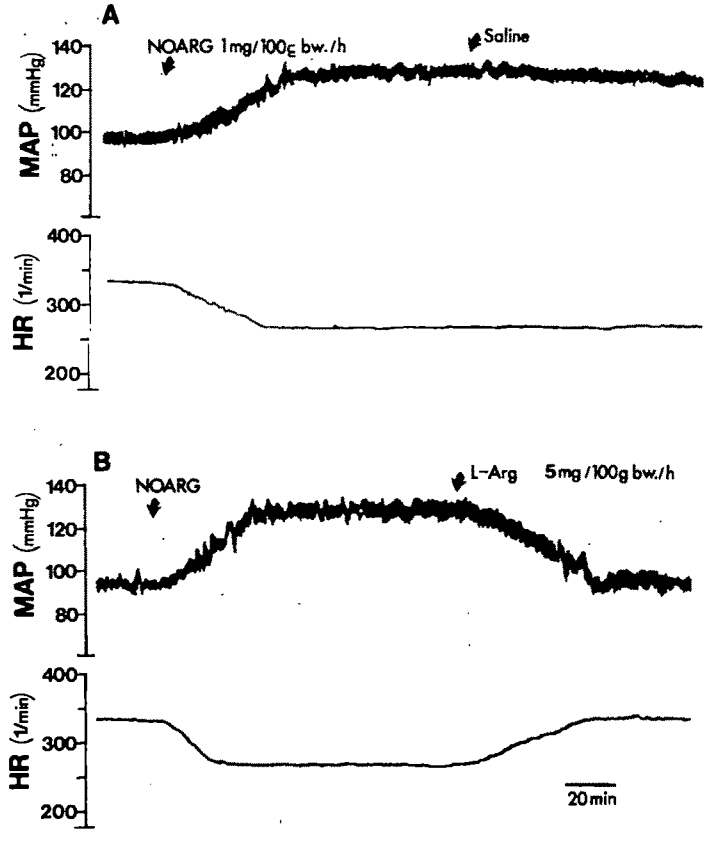

Fig. 3. L-Arginine reversed Nω-nitro-L-arginine–induced vasoconstriction. Chronically catheterized pregnant rats were infused with Nω-nitro-L-arginine (1 mg/100 gm body weight per hour) at rate of 0.5 ml/100 gm body weight per hour. After 2 hours infusion was continued with saline solution **(A)** or L-arginine (5 mg/100 gm body weight per hour) **(B)** at same flow rate. MAP and heart rate were monitored continuously, as described in Material and Methods.

lieved to be the intracellular mediator of endothelium-dependent vasorelaxation.[7] It remains to be clarified whether pregnancy-induced vasodilatation is due chiefly to increased elaboration of nitric oxide by the vascular endothelium or also to an increase in the activity of the nitric oxide–sensitive guanylate cyclase of vascular smooth muscle cells.

It may be relevant to point out that the loss of refractoriness to pressor agents is the hallmark of pregnancy-associated hypertension.[15] Myatt et al.[25] have recently presented evidence that basal release of nitric oxide contributes to maintenance of vascular tone in placental circulation, whereas blockade of prostaglandin synthesis by meclofenamate had no effect on the flow pressure of the placental circulation.[25] Further, an impairment in endothelium-derived relaxing factor release has been observed in vitro in vessels of spontaneously[26] and experimentally hypertensive[27] animals. In the anesthetized rabbit the blockage of endothelium-derived relaxing factor production by N-monomethyl-L-arginine caused a long-lasting arterial blood pressure increase, suggesting that a reduction in the synthesis of nitric oxide may contribute to the pathogenesis of hypertension.[28] Pinto et al.[29] recently found a significantly lower release of endothelium-derived relaxing factor by the umbilical arteries and veins collected from patients with pregnancy-induced hypertension compared with tissues from normal subjects, supporting the hypothesis that impaired endothelium-derived relaxing factor synthesis may be an important factor in the etiology of pregnancy-induced hypertension.

Even though the cyclooxygenase inhibitor indomethacin failed to restore the blunted systemic and renal responsiveness in instrumented, conscious, late-gravid rats,[5] a modulating role for prostacyclin, possibly by interacting in synergistic fashion with endothelium-derived relaxing factor–nitric oxide, as has been demonstrated with respect to platelet aggregation,[30] should not be ruled out. Ahokas and Sibai[31] reported that administration of N-monomethyl-L-arginine to spontaneously hypertensive pregnant rats raised blood pres-

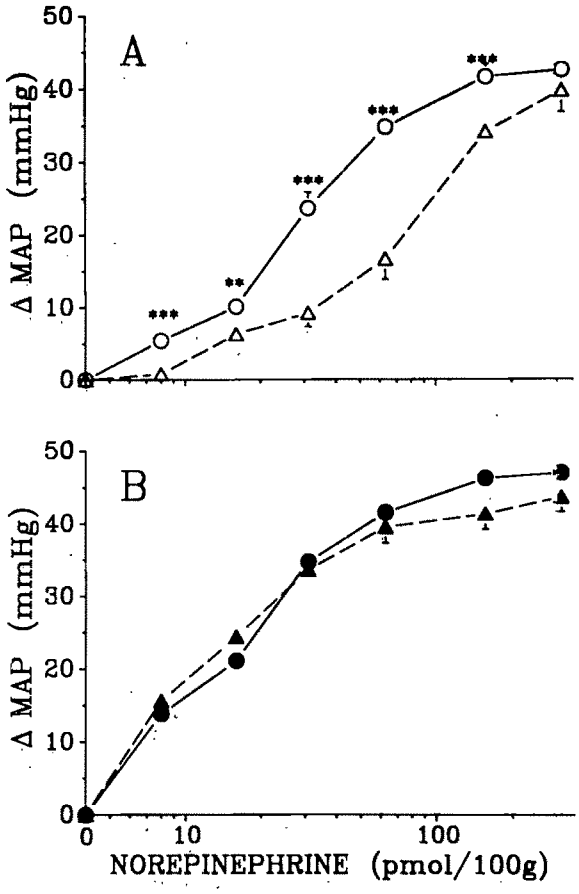

Fig. 6. Pressor responses to norepinephrine in pregnant (△, ▲) and nonpregnant (○, ●) rats during saline solution (*A*) and Nω-nitro-L-arginine (*B*) infusion. sure and blunted pressor responses to angiotensin II; these parameters were unaffected by pretreatment with indomethacin. However, N-monomethyl-L-arginine failed to significantly affect pressor responses to angiotensin II in pregnant normotensive WKY rats. In a recent study Umans et al.[32] also observed a significant increase in MAP of conscious, instrumented rats in response to a single intravenous bolus of N-monomethyl-L-arginine, a less-potent inhibitor of nitric oxide synthesis. However, these investigators failed to detect the blunted pressor responsiveness occurring during normal gestation and failed to detect an increased responsiveness to N-monomethyl-L-arginine in pregnant versus virgin rats. The model used in the current study offers the advantage of comparing the same groups of animals under identical experimental treatments during late gestation and 7 days post partum. This and the choice of inhibitors may account for the apparent discrepancy.

Taken together, the current results and those of other investigators[23-25, 29] provide strong suggestive evidence that endothelium-derived factors play key roles in the regulation of blood pressure in the gravid female to meet the requirements of the changing internal environment of pregnancy.

Role of prostaglandins in the metabolic responses of the fetus to hypoxia

Stuart B. Hooper, PhD, Richard Harding, PhD, Jan Deayton, BSc, and Geoffrey D. Thorburn, MD

Clayton, Victoria, Australia

OBJECTIVE: The effect of inhibiting prostaglandin synthesis on the fetal metabolic response to hypoxemia was examined by infusing indomethacin during periods of reduced maternal uterine blood flow.

STUDY DESIGN: In seven fetal sheep we administered a 6-hour infusion of either indomethacin ($n = 5$), indomethacin plus prostaglandin E_2, or a vehicle solution ($n = 5$). The last 4 hours of each infusion period coincided with a period of fetal hypoxemia induced by reduced maternal uterine blood flow.

RESULTS: During reduced maternal uterine blood flow indomethacin infusions caused a significantly greater reduction in pH_A (reduced from 7.36 ± 0.01 to 7.10 ± 0.02) than both the vehicle (from 7.36 ± 0.01 to 7.20 ± 0.03) and indomethacin plus prostaglandin E_2 infusions (from 7.36 ± 0.01 to 7.18 ± 0.02). Before reduced maternal uterine blood flow was induced, indomethacin significantly elevated fetal plasma glucose and lactate concentrations from 0.6 ± 0.04 and 2.2 ± 0.1 to 1.3 ± 0.2 and 6.7 ± 0.7 mmol/L, respectively. During reduced maternal uterine blood flow indomethacin caused a significantly greater increase in plasma glucose and lactate concentrations than the vehicle; plasma glucose and lactate concentrations increased to a maximum of 1.8 ± 0.2 and 22.7 ± 0.8 mmol/L, respectively, during indomethacin infusions compared with 1.1 ± 0.1 and 15.7 ± 1.7 mmol/L, respectively, during vehicle infusions. The addition of prostaglandin E_2 to the indomethacin infusion prevented the enhanced increase in glucose and lactate concentrations during reduced maternal uterine blood flow and caused a significant increase in fetal plasma insulin concentrations from 12.6 ± 0.7 to 60.9 ± 28.1 μU/ml.

CONCLUSION: The inhibition of prostaglandin synthesis during fetal hypoxemia alters the metabolic response of the fetus, leading to a severe metabolic acidosis. (Am J Obstet Gynecol 1992;166:1568-75.)

Key words: Fetus, hypoxia, asphyxia, indomethacin, glucose, lactate, insulin

Fetal hypoxia is a common cause of fetal morbidity and mortality and can result from a number of causes, including umbilical cord occlusion, maternal cigarette smoking, and reduced uteroplacental circulation. The blood gas and pH changes and many of the endocrine, biophysical, and cardiovascular responses that occur in the fetus during acute periods of hypoxemia are not sustained if the hypoxemia is prolonged.[1-4] In particular the fetal arterial acidosis, which develops initially after reducing maternal uterine blood flow, is corrected after 12 to 16 hours.[3,4] We have suggested that this correction in fetal blood pH results from a metabolic adaptation to the hypoxemia[4]; our study is directed toward an understanding of the mechanisms involved in this adaptation.

Prostaglandin E_2 (PGE_2) is considered to be an important circulating fetal hormone released by the placenta.[5-7] Fetal plasma PGE_2 concentrations gradually increase in an exponential-like manner toward term[7] and can be precociously elevated by fetal hypoxemia,[4] hypoglycemia,[7,8] and hyperthermia.[9] In addition, PGE_2 is thought to play an important metabolic role in the fetus by regulating insulin release,[10] and PGE_2 has recently been identified as the placental factor that prevents catecholamine-mediated brown fat metabolism in the fetus.[11]

In a previous study we suggested that correction of fetal arterial acidosis, which occurred during prolonged hypoxia, primarily resulted from an increase in the uptake and metabolism of glucose and lactate by the fetus.[4] Because we also observed that the increase in fetal arterial pH during prolonged hypoxemia closely followed the increase in fetal plasma PGE_2 concentrations, the aim of the present study was to determine the role of PGE_2 in the fetal metabolic adaptation to hypoxemia. In particular we wished to determine the effect of inhibiting prostaglandin release during fetal hypoxemia on fetal plasma glucose, lactate, and insulin concentrations. We hypothesized that the gradual increase in circulating PGE_2 concentrations in the fetus

during hypoxemia plays an important metabolic role by reducing fetal blood glucose and, hence, lactate concentrations.

Material and methods

Animal preparation. Surgery was performed under aseptic conditions on seven Border Leicester × Merino ewes between 110 and 117 days of gestation (term is 145 days). Anesthesia was induced with 5% thiopental sodium in water (intravenously) and was maintained after tracheal intubation with 1.5% halothane (oxygen/nitrous oxide, 50:50 vol/vol). In all ewes polyvinyl catheters (SV116, Dural Plastics, Sydney, Australia) were implanted into the maternal jugular vein and amniotic cavity. An adjustable clamp[12] was placed around the maternal common internal iliac artery to produce controlled reductions in maternal uterine blood flow.[13, 14]

In each fetus polyvinyl catheters (SV65, Dural Plastics) were implanted into the carotid artery and jugular vein. A polyvinyl catheter (SV116) was also implanted into the trachea of the fetus to detect fetal breathing movements. Antibiotics (2 ml Streptopen intramuscularly, Glaxovet, Australia) were administered to each fetus before the uterine incision was closed. Fetal catheters and the control cable for the vascular clamp were exteriorized through an incision in the right flank of the ewe. The ewes were allowed to recover for at least 5 days after surgery before experimentation.

Experimental protocol. Three separate 8-hour experiments were performed, each consisting of a 6-hour infusion period and a 2-hour recovery period. The last 4 hours of the 6-hour intravenous infusion corresponded to a period of moderate fetal asphyxia induced by reducing maternal uterine blood flow.[14] The three experiments differed by the type of infusion administered to the fetus: (a) a vehicle solution, (b) indomethacin (17 gm/min), or (c) indomethacin (17 gm/min) plus PGE_2 (2 gm/min). Fetal arterial blood samples were collected before the infusion (−2 hours), immediately before the period of reduced maternal uterine blood flow (0 hours), and at 0.5, 1, 2, 4, and 6 hours after the onset of reduced maternal uterine blood flow for the measurement of Pa_{O_2}, Pa_{CO_2}, pH_A, fetal arterial blood oxygen saturation (Sa_{O_2}), and glucose and lactate concentrations. Fetal arterial blood samples were also collected for the measurement of insulin concentrations at −2, 0, 2, and 4 hours. Fetuses were allowed to recover for ≤5 days between experiments.

Fetal Pa_{O_2}, Pa_{CO_2}, and pH_A were measured with a blood gas and acid base analyzer (ABL30, Radiometer, Denmark); fetal Sa_{O_2} was measured with a hemoximeter (OSM2, Radiometer). Fetal arterial pressure and heart rate were recorded continuously on a polygraph (7D, Grass) throughout each experiment. Arterial pressures were recorded after subtraction of amniotic fluid pressure. These experiments adhere to the Monash University guidelines on the care and use of experimental animals.

Insulin assay. Fetal plasma insulin concentrations were measured with a human insulin radioimmunoassay kit (code IM.78, Amersham, United Kingdom) modified for ovine fetal plasma. The antisera to human insulin, human insulin standards (range 0 to 320 μU/ml), iodine 125–labeled insulin, and assay buffers were provided with the kit. The manufacturer's protocol was used except for the following modifications: to increase the sensitivity of the assay, the concentration of antisera and ^{125}I-labeled insulin was one quarter and one half, respectively, of the concentration recommended; the assay was incubated overnight at 4° C, and bound and free insulin was separated with polyethylene glycol 6000 (10%; 0.03% sodium azide). All assay tubes were centrifuged at 2500 rpm for 20 minutes at 4° C (Beckman J6B) before the supernatant was aspirated off. The radioactivity remaining in the pellet was quantified using a gamma counter (Crystal 5400, Packard, USA). The intraassay coefficient of variation was 11.1% ($n = 16$) at an insulin concentration of 72.8 ± 2.0 μU/ml of fetal plasma. No significant deviation from parallelism ($p > 0.1$) was found between a standard curve in buffer, a standard curve in plasma, and different volumes of a single plasma sample. A significant ($p < 0.005$) correlation was found between the amount of insulin added to plasma and the amount measured by the assay ($y = 0.98x + 0.58$, $r = 0.998$).

Plasma PGE_2 glucose and lactate concentrations. Fetal plasma PGE_2 concentrations were measured by radioimmunoassay with antisera and procedures previously described.[7] Fetal plasma glucose concentrations were measured enzymatically by a previously described method.[15] Fetal plasma lactate concentrations were also measured enzymatically with a glucose-lactate analyzer (2300GL, Yellow Springs Instruments).

Statistical analysis. The results are presented as mean ± SEM. Data on fetal blood gases and pH_A and fetal plasma, PGE_2, glucose, lactate, and insulin concentrations (after log transformation) were analyzed by a three-way analysis of variance with treatment (type of infusion), time, and animals as factors. All three experiments were completed in only four of the seven animals studied. Analyses of variance were performed only with these four fetuses. If a significant effect of treatment was found between any of the treatments, the significant treatment was analyzed separately by a two-way analysis of variance with animals and time as factors. This analysis was followed by a Student–Newman-Keuls multiple-range test for differences between time periods. Differences between treatments for a

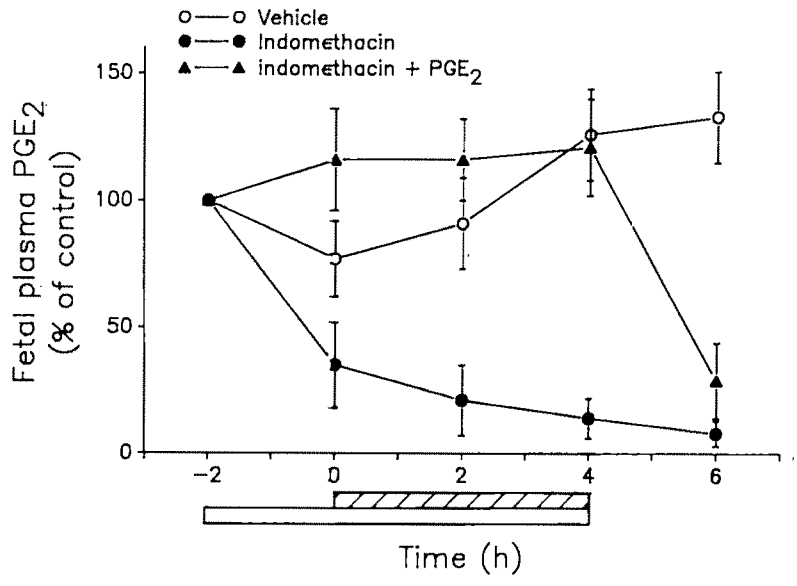

Fig. 1. Fetal plasma PGE_2 concentrations expressed as a percentage of preinfusion control values during either a 6-hour vehicle *(open circles)*, indomethacin *(solid circles)*, or indomethacin plus PGE_2 *(triangles)* infusion. The period of reduced maternal uterine blood flow *(hatched bar)* coincided with the last 4 hours of the 6-hour infusions *(open bar)*.

given time period were analyzed by a nonpaired Student's t test. Unless otherwise stated, the level of significance reported in the text is $p < 0.05$.

Results

Fate of fetuses. All fetuses survived to or near term (140.1 ± 0.8 days), at which time the ewes and fetuses were killed by an overdose of pentobarbital sodium All fetuses were classified as being healthy at the start of each experiment as judged by their blood gas and acid-base status.

Fetal plasma PGE_2 concentrations. The vehicle infusion alone did not significantly affect fetal plasma PGE_2 concentrations, whereas inducing reduced maternal uterine blood flow during the vehicle infusion caused an increase in PGE_2 concentrations from a mean control value of 4.3 ± 1.1 nmol/L to a maximum of 5.8 ± 1.0 nmol/L after 4 hours of reduced maternal uterine blood flow (Fig. 1). The infusion of indomethacin caused a significant reduction in fetal plasma PGE_2 concentrations from a mean control value of 5.7 ± 1.7 nmol/L to below the sensitivity of the assay (in all except one experiment) 2 hours after starting the infusion. The addition of PGE_2 to the indomethacin infusion maintained fetal plasma PGE_2 concentrations at preinfusion levels; PGE_2 concentrations were similar before the start of the infusion (4.2 ± 1.4 nmol/L) compared with 6 hours after the start of the infusion (5.1 ± 1.6 nmol/L). Two hours after the completion of the indomethacin plus PGE_2 infusion fetal plasma PGE_2 concentrations had significantly decreased to 1.2 ± 1.0 nmol/L.

Blood gas and pH measurements. No effect of infusion type was found on the changes in fetal Sao_2, Pao_2 and $Paco_2$ in response to reduced maternal uterine blood flow, indicating that the level of hypoxemia was similar in all three groups (Fig. 2). During the vehicle infusion reduced maternal uterine blood flow significantly decreased fetal Pao_2 and Sao_2 from control values of 23.5 ± 0.2 mm Hg and 57.3% ± 3.0% to 14.7 ± 1.1 mm Hg and 23.9% ± 1.8%, respectively, after 1 hour. Similar decreases were observed during the other two infusions. In contrast, a significant effect of infusion type was found on the changes in pH_A in response to reduced maternal uterine blood flow. Before reduced maternal uterine blood flow was induced the indomethacin and indomethacin plus PGE_2 infusions, but not vehicle infusions, caused a significant reduction in pH_A compared with respective preinfusion control values (Fig. 2). During vehicle infusions reduced maternal uterine blood flow caused a significant reduction in pH_A from a control value of 7.36 ± 0.01 to a minimum of 7.20 ± 0.03 after 2 hours. Compared with vehicle infusions indomethacin infusions resulted in a lower pH_A at 1, 2, and 4 hours after inducing reduced maternal uterine blood flow (Fig. 2); fetal pH_A decreased from a mean control value of 7.36 ± 0.01 to a minimum of 7.10 ± 0.02 after 2 hours of reduced maternal uterine blood flow. The addition of PGE_2 to the indomethacin infusion reversed the effects of indomethacin alone during reduced maternal uterine blood flow (Fig. 2). During the indomethacin plus PGE_2 infusions, fetal pH_A decreased from a control value of 7.36 ± 0.01 to a minimum of 7.18 ± 0.02 at

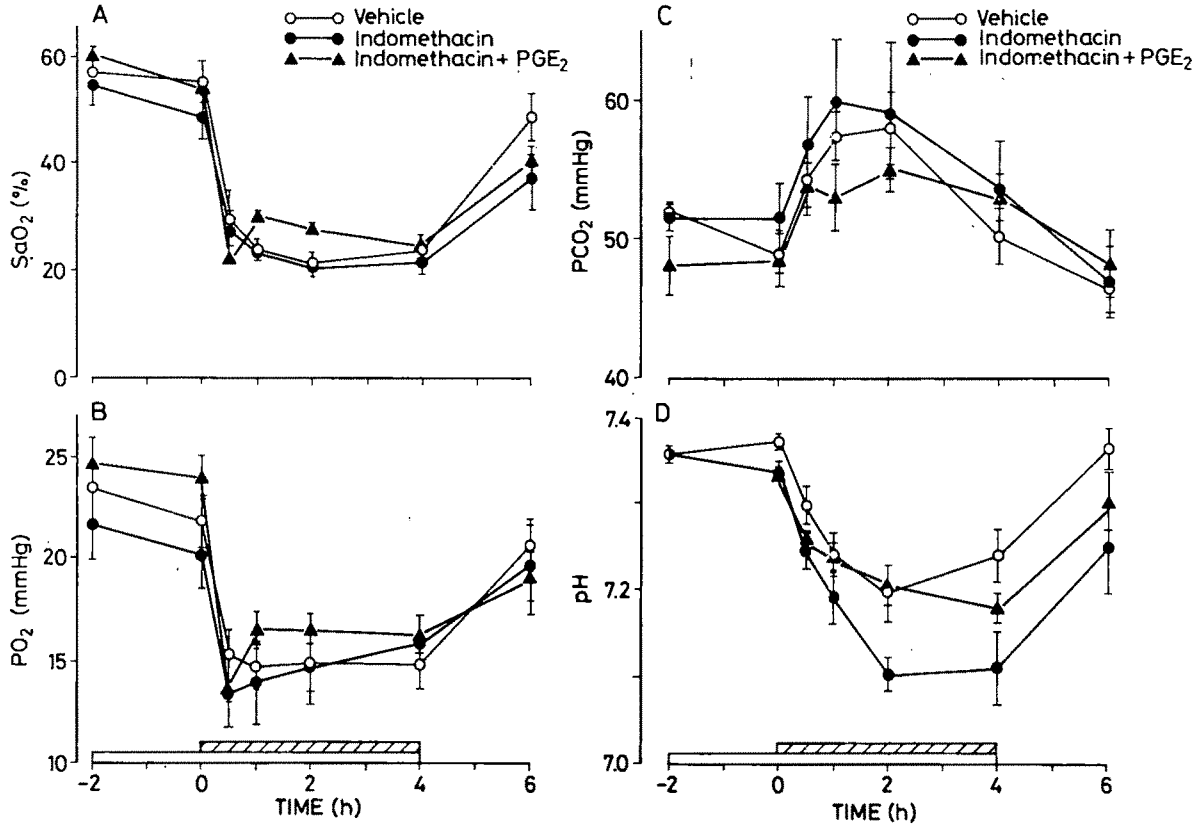

Fig. 2. SaO_2 **(A),** PaO_2 **(B),** $PaCO_2$ **(C),** and pH_A **(D)** measured during either a 6-hour vehicle *(open circles)*, indomethacin *(solid circles)*, or indomethacin plus PGE_2 *(triangles)* infusion. The period of reduced maternal uterine blood flow *(hatched bar)* coincided with the last 4 hours of the 6-hour infusions *(open bar)*.

4 hours after inducing reduced maternal uterine blood flow.

Fetal plasma glucose concentrations. A significant effect of infusion type was found on the changes in fetal plasma glucose concentrations. During vehicle infusions reduced maternal uterine blood flow caused a significant elevation in fetal plasma glucose concentrations from a preinfusion control value of 0.60 ± 0.09 mmol/L to a maximum of 1.1 ± 0.1 mmol/L after 30 minutes of reduced maternal uterine blood flow. Fetal plasma glucose concentrations remained elevated for the duration of the experiment (Fig. 3, *A*). Before reduced maternal uterine blood flow was induced, both the indomethacin and indomethacin plus PGE_2 infusions, but not vehicle infusion, caused a significant increase in fetal plasma glucose concentrations. During indomethacin infusions, glucose concentrations increased from a mean control value of 0.6 ± 0.04 to 1.3 ± 0.2 mmol/L (Fig. 3, *A*). Inducing reduced maternal uterine blood flow during the indomethacin infusion caused a further significant increase in fetal plasma glucose concentrations to a maximum of 1.8 ± 0.2 mmol/L after 1 hour of reduced maternal uterine blood flow. The addition of PGE_2 to the indomethacin infusion prevented the additional increase in glucose concentrations that occurred during reduced maternal uterine blood flow (Fig. 3, *A*).

Fetal plasma lactate concentrations. The three types of infusion had significantly different effects on fetal plasma lactate concentrations (Fig. 3, *B*). During vehicle infusions, fetal plasma lactate concentrations were significantly elevated by reduced maternal uterine blood flow from a control value of 2.4 ± 0.2 mmol/L to a maximum of 15.7 ± 1.7 mmol/L after 4 hours. The infusion of indomethacin before the induction of reduced maternal uterine blood flow caused a significant elevation in fetal plasma lactate concentrations from a preinfusion control value of 2.2 ± 0.1 to 6.7 ± 0.7 mmol/L. The induction of reduced maternal uterine blood flow during the indomethacin infusion caused a further significant elevation in fetal plasma lactate concentrations to a maximum of 22.7 ± 0.8 mmol/L after 4 hours of reduced maternal uterine blood flow. The addition of PGE_2 to the indomethacin infusion prevented the indomethacin-induced increase in fetal plasma lactate concentrations during normoxia and reduced the increase in lactate concentrations observed during an indomethacin infusion in the presence of reduced maternal uterine blood flow. The increases in fetal plasma lactate concentrations during reduced ma-

Fetal plasma glucose **(A)** and lactate **(B)** concentrations measured during either a 6-hour vehicle *(open circles)*, indomethacin *(solid circles)*, or indomethacin plus PGE_2 *(triangles)* infusion. The period of reduced maternal uterine blood flow *(hatched bar)* coincided with the last 4 hours of the 6-hour infusions *(open bar)*.

ternal uterine blood flow were similar during vehicle infusions and indomethacin plus PGE_2 infusions.

Fetal plasma insulin concentrations. The three types of infusion had significantly different effects on the concentration of insulin in fetal plasma. The infusion of indomethacin alone had no significant effect on fetal plasma insulin concentrations during normoxia. During vehicle infusions, reduced maternal uterine blood flow caused a small reduction in fetal plasma insulin concentrations from a control value of 9.5 ± 0.7 μU/ml to a minimum of 5.9 ± 0.3 μU/ml after 4 hours of reduced maternal uterine blood flow (Fig. 4). Similarly, inducing reduced maternal uterine blood flow during indomethacin infusions caused a decrease in fetal plasma insulin concentrations from a control value of 14.7 ± 2.2 to a minimum of 6.5 ± 0.3 μU/ml after 2 hours of reduced maternal uterine blood flow. The addition of PGE_2 to the indomethacin infusion caused a large increase in fetal plasma insulin concentrations during normoxia from a preinfusion control value of 12.6 ± 0.7 to 60.9 ± 28.1 μU/ml after 2 hours. In the subsequent reduced maternal uterine blood flow period fetal plasma insulin concentrations decreased to a minimum value of 19.6 ± 5.2 μU/ml after 4 hours (Fig. 4).

Comment

In this study we have obtained evidence to support the contention that increased placental PGE_2 production plays an important role in the metabolic adaptation of the fetus to prolonged hypoxia. We have demonstrated that the inhibition of prostaglandin synthesis enhances the increase in fetal plasma glucose and lactate concentrations that occur during reduced maternal uterine blood flow. The enhanced increase in plasma lactate concentrations undoubtedly contributes to the severe reduction in fetal pH_A which, if sustained, causes fetal death (Hooper SB, Harding R, Thorburn GD. Unpublished observations). The addition of PGE_2 to the indomethacin infusion, however, prevented this augmented fetal acidemia, hyperglycemia, and hyperlactemia during reduced maternal uterine blood flow and stimulated a large increase in fetal plasma insulin concentrations.

During vehicle infusions PGE_2 concentrations were significantly elevated after 4 hours of reduced maternal uterine blood flow, which supports our earlier observation.[4] The infusion of indomethacin, a potent inhibitor of prostaglandin synthesis,[16] rapidly decreased fetal plasma PGE_2 concentrations; they remained low during the subsequent reduced maternal uterine blood flow period. The addition of PGE_2 to the indomethacin infusion maintained circulating fetal plasma PGE_2 concentrations at preinfusion levels for the duration of the infusion (Fig. 1). However, it is unlikely that the dose of PGE_2 administered was sufficient to sustain the normal delivery of PGE_2 to some tissues (e.g., liver) and, more importantly, to increase the delivery to a level that would occur during reduced maternal uterine blood flow.[4] The major source of circulating PGE_2 in the fetus is the placenta,[6, 7] and umbilical vein PGE_2 concentrations are much higher than the concentrations circulating in the fetus.[7] Because 75% of the blood supply to the fetal liver is derived from the umbilical vein,[17] the fetal liver is therefore normally exposed to higher concentrations of PGE_2 than the concentrations that circulate in fetal blood. This could explain why PGE_2 did not reverse all of the effects of insulin administration.

The infusion of indomethacin during reduced maternal uterine blood flow caused a much greater reduction in pH_A than when the vehicle was infused. During reduced maternal uterine blood flow the reduction in pH_A most probably results from the elevation in $Paco_2$ (respiratory acidosis), the elevation in blood lactate, and possibly fatty acid concentrations (metabolic acidosis), although these were not measured. The greater reduction in pH_A during reduced maternal

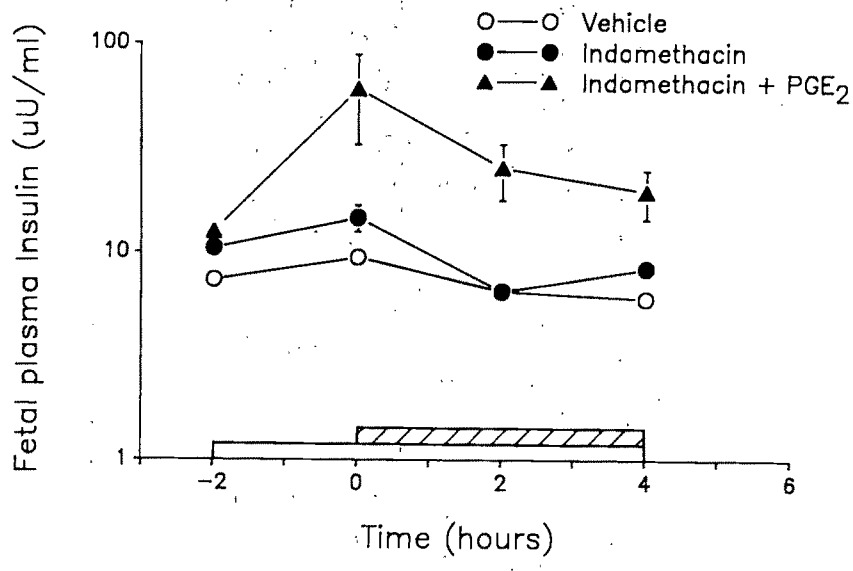

Fig. 4. Fetal plasma insulin concentrations plotted on a log scale, measured during either a 6-hour vehicle *(open circles)*, indomethacin *(solid circles)*, or indomethacin plus PGE_2 *(triangles)* infusion. The period of reduced maternal uterine blood flow *(hatched bar)* coincided with the last 4 hours of the 6-hour infusions *(open bar)*.

uterine blood flow in indomethacin compared with vehicle infusions must have been metabolic in origin because the elevation in $PaCO_2$ was similar in both experiments, whereas blood lactate concentrations were greater with indomethacin. The addition of PGE_2 to the indomethacin infusion prevented this enhanced acidosis, presumably by preventing the increase in lactate concentrations; however, it is also possible that PGE_2 reduced fatty acid concentrations by decreasing lipolysis in adipose tissue.[18] If reduced maternal uterine blood flow and the indomethacin infusions were continued for a longer period of time (>6 hours), these fetuses would probably have died. In two preliminary experiments we considered it appropriate to induce reduced maternal uterine blood flow during an indomethacin infusion for at least 12 hours because PGE_2 increases relatively slowly during reduced maternal uterine blood flow and is significant only after 4 hours.[4] In these preliminary experiments both fetuses became severely acidotic (pH 6.9 to 7.0) and died between 6 and 8 hours after inducing reduced maternal uterine blood flow (Hooper, Harding, and Thorburn, unpublished observations). This observation and those presented in our study clearly demonstrate the detrimental effects that indomethacin has on a hypoxemic fetus. Furthermore, these effects could explain the unaccounted fetal deaths that have occurred in utero after the administration of indomethacin to prevent premature labor in human beings.[19]

The control of blood glucose concentrations in the fetus is primarily dependent upon maternal blood glucose concentrations, insulin production by the fetal pancreas, fetal glucose use, and glucose production or storage by the liver.[20] Gluconeogenesis is a very important source of blood glucose in adult ruminants,[21] but although the fetal sheep liver has all the necessary enzymes it is believed that this metabolic pathway does not operate until after birth.[22, 23] It is not known, however, whether this pathway can be activated during fetal hypoxemia. The finding in this study that an indomethacin infusion during normoxia causes an elevation in fetal plasma glucose concentrations has been reported previously.[24] The mechanism underlying this increase is not known although it probably results from an increase in glucose release from the liver because insulin concentrations were not altered by indomethacin.

PGE_2 failed to reverse the effect of indomethacin on fetal blood glucose concentrations during normoxia, which could mean that (1) the dose of PGE_2 administered was insufficient to increase PGE_2 concentrations in the umbilical vein to normal levels, (2) PGE_2 is the wrong prostaglandin, or (3) the failure was due to a side effect of indomethacin unrelated to prostaglandin synthesis. One known side effect of indomethacin is the inhibition of phosphodiesterase activity, although this only occurs at much higher doses than that used in our study.[25] Inhibition of phosphodiesterase activity would cause a sustained elevation in intracellular cyclic adenosine monophosphate (cAMP) concentrations by preventing the breakdown of cAMP. As discussed below, an increase in intracellular cAMP concentrations in liver tissue would decrease glycolysis and promote gluconeogenesis and glucose release.[26] Other known

side effects of indomethacin are oligohydramnios,[5, 27] possibly caused by reduced fetal urine production, a reduction in cerebral blood flow in fetal sheep,[24] and an increase in vascular tone of the ductus arteriosus.[28]

Fetal plasma catecholamine concentrations are elevated by fetal hypoxia whether it is induced by maternal hypoxia[29] or reduced maternal uterine blood flow.[4] The increase in fetal plasma catecholamine concentration is believed to be responsible for the increase in glucose concentration during fetal hypoxemia.[30] Catecholamines promote an increase in glucose release by the liver, which is mediated by β-adrenergic receptors and an increase in cAMP levels.[31] Catecholamines also inhibit insulin release from the pancreas, an action mediated by α-adrenergic receptors and a decrease in cAMP levels.[18] The increases in fetal plasma glucose concentrations we observed during reduced maternal uterine blood flow (vehicle infusion) are similar to those reported previously during fetal hypoxia caused by maternal hypoxia.[30] The infusion of indomethacin, however, caused a greater increase in fetal blood glucose concentrations after the induction of reduced maternal uterine blood flow. The mechanism by which indomethacin enhances this increase in fetal blood glucose during reduced maternal uterine blood flow is not known. It is highly likely, however, to be mediated by an inhibition of PGE_2 synthesis because the addition of PGE_2 to the indomethacin infusion prevented this increase. We suggest that PGE_2 may antagonize some of the biochemical actions of the catecholamines in utero by exerting opposing actions on tissue levels of cyclic adenosine monophosphate. For example, we speculate that PGE_2 acts on the fetal liver to lower tissue cAMP concentrations. Increased cAMP levels in the liver decrease glycolysis and promote an increase in gluconeogenesis and glycogenolysis, leading to increased hepatic glucose release. If PGE_2 acts on the fetal liver as it does in adipose tissue,[18] increased PGE_2 concentrations would promote a reduction in liver cAMP levels; this would enhance glycogen synthesis and glycolysis and inhibit glycogenolysis and gluconeogenesis, thereby decreasing glucose release. Thus reducing circulating PGE_2 concentrations during reduced maternal uterine blood flow would lead to an unopposed action of the catecholamines on liver cAMP levels, leading to increased glucose production.

The concept that PGE_2 can oppose the action of catecholamines in utero is supported by the finding that PGE_2 release from the placenta prevents brown-fat metabolism (nonshivering thermogenesis) in the fetus.[11] In newborn lambs brown-fat metabolism is activated by adrenergic stimulation and is mediated by β-adrenergic receptors, which increase cAMP concentrations.[32] PGE_2 is known to inhibit lipolysis in adipose tissue by reducing cAMP concentrations[18] and probably has a similar action on brown adipose tissue to prevent nonshivering thermogenesis in the fetus.[11] In our study, in which fetal PGE_2 concentrations were reduced by indomethacin and sympathoadrenal activity was increased by reduced maternal uterine blood flow,[4] it seems likely that lipolysis would have been stimulated and that the release of fatty acids would have contributed to the observed acidosis.

The action of catecholamines on the β-islet cells of the pancreas to inhibit insulin release is mediated by α-adrenergic receptors leading to a reduction in cAMP concentrations.[26] In these experiments PGE_2 stimulated a large increase in insulin concentrations, again demonstrating an opposing action to the catecholamines. We speculate that PGE_2 acts on membrane-bound adenylcyclase receptors, resulting in an increase in cAMP concentrations and thus insulin release.

The indomethacin infusion during normoxia caused an increase in fetal plasma lactate concentrations, which probably resulted from the increase in plasma glucose concentrations. The addition of PGE_2 to the indomethacin infusion prevented this increase in lactate concentrations, probably because of the large increase in plasma insulin concentrations and possibly also because of the suppression of glycogenolysis. Increased plasma insulin concentrations would promote the uptake of glucose for oxidative metabolism or storage as glycogen. During fetal hypoxia the increase in fetal plasma glucose concentrations is believed to be largely responsible for the increase in fetal blood lactate concentrations because of the anaerobic metabolism of fetal glucose primarily by the placenta.[30] Thus the increased fetal blood glucose could account for the enhanced increase in circulating fetal plasma lactate concentrations caused by indomethacin during reduced maternal uterine blood flow. The addition of PGE_2 prevented this effect of indomethacin during reduced maternal uterine blood flow, probably by elevating insulin concentrations and suppressing glucose production.

We have demonstrated that during fetal hypoxemia indomethacin has profound metabolic effects on the fetus; if the hypoxia or infusion is prolonged, the fetus is at risk of fatal acidemia. A similar finding has been observed after the inhibition of prostaglandin synthesis during another form of fetal stress, hyperthermia.[9] During hyperthermia the infusion of 4-aminoantipyrine, a prostaglandin synthetase inhibitor, caused a large increase in fetal plasma glucose concentrations and a rapid decrease in fetal pH; 4 of 10 fetuses died from this treatment.[9] We contend, therefore, that an elevation in placental prostaglandin synthesis, probably PGE_2, plays an integral role in the fetal metabolic adaptation to stress, possibly by leading to a gradual suppression of the metabolic actions of the catecholamines.

We are indebted to K. Billings for her expert technical assistance and to A. Satragno for surgical assistance.

New Haven, Connecticut, Detroit, Michigan, and Cambridge, Massachusetts

OBJECTIVE: Our objective was to determine if labor (term and preterm) and microbial invasion of the amniotic cavity were associated with changes in amniotic fluid concentrations of tumor necrosis factor.
STUDY DESIGN: Amniotic fluid was retrieved by transabdominal amniocentesis from 269 women in the following groups: midtrimester (n = 38), preterm labor with intact membranes (n = 52), preterm premature rupture of membranes (n = 74), term in active labor (n = 34), and term not in labor (n = 21). Fluid was cultured for aerobic and anaerobic bacteria and for *Mycoplasma* species. Tumor necrosis factor was measured with a commercially available enzyme-linked immunosorbent assay validated for amniotic fluid (sensitivity 60 pg/ml).
RESULTS: Amniotic fluid from pregnant women in the second and third trimesters who were not in labor did not contain tumor necrosis factor. Among women in preterm labor, 92.3% (12/13) of patients with a positive amniotic fluid culture had detectable tumor necrosis factor in the amniotic fluid (median 820 pg/ml, range <60 to 2340 pg/ml). In contrast, only 10.2% (4/39) of women with a negative amniotic fluid culture had detectable tumor necrosis factor. Histopathologic chorioamnionitis was found in all patients who had a positive amniotic fluid culture, and tumor necrosis factor was detectable in the amniotic fluid of all but one of these patients. Among women in active labor at term, 25% (21/84) had detectable tumor necrosis factor in the amniotic fluid. Tumor necrosis factor was detected more frequently in the amniotic fluid of patients with a positive amniotic fluid culture than in patients with a negative culture (46.6% [7/15] vs 20.2% [14/69], p = 0.047). Amniotic fluid concentrations of tumor necrosis factor were significantly higher in patients with preterm premature rupture of membranes, labor, and a positive amniotic fluid culture than in the other subgroups of patients with preterm premature rupture of membranes.
CONCLUSION: Parturition in the setting of microbial invasion of the amniotic cavity is associated with activation of the cytokine network as demonstrated by the detection of tumor necrosis factor in human amniotic fluid. (AM J OBSTET GYNECOL 1992;166:1576-87.)

Key words: Labor, parturition, amniotic fluid, tumor necrosis factor, prematurity, preterm labor, term labor, immunoassay, cytokine

There is a strong association between systemic and intrauterine infection and preterm labor and delivery.[1] A growing body of evidence suggests that cytokines, which are capable of stimulating prostaglandin production by intrauterine tissues, may serve as mediators of parturition in the setting of infection.[2-5] Tumor necrosis factor (TNF) is a cytokine produced by activated macrophages in response to a wide variety of stimuli, including bacterial products, viruses, and parasites. It has been proposed that this cytokine may participate in the mechanisms of human parturition associated with infection.[4] TNF is produced by human decidua in response to bacterial products[6, 7] and stimulates prostaglandin production by amnion[4] and decidua.[5]

Previously, we have identified the presence of TNF in the amniotic fluid of women with microbial invasion of the amniotic cavity and preterm labor by means of the L929 bioassay.[4] This bioassay, like others for cytokines, is time consuming, laborious, semiquantitative, and is affected by the presence of inhibitors in biologic fluids. Clinical application of TNF determinations to obstetric practice requires the availability of sensitive, rapid, and simple assays for its detection. Recently, immunoassays for this cytokine have become available. The purpose of this study was to validate an immunoassay for the quantitation of TNF in human amniotic fluid and to examine the changes in amniotic fluid concentrations of this cytokine in the setting of labor (term and preterm) and microbial invasion of the amniotic cavity.

Material and methods

Study design. A cross-sectional study was conducted according to the results of amniotic fluid cultures, ges-

tational age, and labor status. Five groups were identified for study purposes (Table I). Group 1 consisted of women in the midtrimester of pregnancy (gestational age 16 to 18 weeks) who were undergoing amniocentesis for genetic indications (maternal age >35 years) (n = 38), and group 2 consisted of women at term (38 to 39 weeks) who had amniocentesis for the assessment of fetal lung maturity before elective cesarean section (n = 21). All these patients had a negative amniotic fluid culture. Group 3 consisted of women admitted with preterm labor and intact membranes (n = 52); this group was subdivided according to the results of amniotic fluid culture and response to tocolysis: women with a negative amniotic fluid culture who responded to tocolysis and were delivered at term (n = 23), women with a negative culture who failed to respond to tocolysis and were delivered of a preterm neonate (n = 16), and women with a positive culture who were delivered prematurely (n = 13). Group 4 consisted of women with preterm premature rupture of membranes (n = 74). This group was subdivided according to the presence of labor at the time of amniocentesis and the results of the amniotic fluid culture: women with a negative culture and without preterm labor (n = 26); women with a negative culture but with preterm labor (n = 15); women with a positive culture but without preterm labor (n = 11), and women with a positive culture and preterm labor (n = 22). Group 5 consisted of women in spontaneous active labor at term with intact membranes (n = 84). This group was subdivided according to the results of amniotic fluid cultures: patients with a negative culture (n = 69) and patients with a positive culture (n = 15).

Premature rupture of membranes was defined as amniorrhexis before the onset of spontaneous labor. Nitrazine, pooling, and ferning tests were performed in all women in labor to exclude leakage of amniotic fluid into the vagina. Premature rupture of membranes was diagnosed if at least two of the three tests were positive. Pelvic examinations were not performed at the time of amniocentesis, because this could result in an increased risk of infection.[8] Tocolytic agents were not used in patients with preterm premature rupture of membranes.

Preterm labor was defined as the presence of regular uterine contractions with a frequency of at least two every 10 minutes and with changes in the cervical Bishop's score occurring before 37 completed weeks. Ritodrine was administered intravenously as the tocolytic agent to all patients according to a protocol described elsewhere.[9] Amniocentesis was performed before the initiation of therapy. Failure of tocolysis was diagnosed when cervical dilatation progressed beyond 5 cm or delivery occurred.

Retrieval of amniotic fluid. Amniotic fluid was retrieved by transabdominal amniocentesis in all women in this study. Amniocentesis is offered in our institution to all patients with the diagnosis of preterm labor for microbiologic and fetal lung maturity studies. Women in active labor at term (group 5) were ascertained by searching our obstetric data base. They were identified as patients who met the following criteria: (1) amniocentesis performed because of suspected preterm labor with intact membranes on the basis of uncertain dates, (2) results of amniotic fluid studies (lecithin/sphingomyelin ratio, foam stability test, shake test) consistent with fetal lung maturity, (3) delivery within 24 hours of amniocentesis, (4) neonatal birth weight >2500 gm, (5) pediatric examination (Dubowitz method) consistent with a gestational age >37 weeks, and (6) absence of respiratory distress syndrome or any other neonatal complication attributable to preterm birth. The identification number of patients fulfilling this criterion was cross-referenced with samples stored in our amniotic fluid bank.

Table I. Patient population

Infection	15

A sample of amniotic fluid was sent for microbiologic studies. The remaining fluid was centrifuged at 200g for 10 minutes at 4° C, divided in units of 300 μl per vial, and stored in polypropylene tubes at −70° C until assayed. Samples were not subjected to freeze-thaw cycles before assay.

Microbiologic culture technique. Amniotic fluid was transported to the laboratory in a capped plastic syringe immediately after collection. These conditions precluded air contact with the specimen. Plating occurred within 30 minutes of collection in all cases. Amniotic fluid was cultured for aerobic and anaerobic bacteria and *Mycoplasma* by methods previously described.[10] The Gram stain of amniotic fluid was used for patient management. Patients with a positive Gram stain received antibiotics (generally ampicillin and gentamicin) and had tocolysis discontinued.

Quantitation of TNF. Amniotic fluid TNF was measured with a commercially available, enzyme-linked immunoassay (ELISA) (FactorTest-Human TNF-α, Gen-

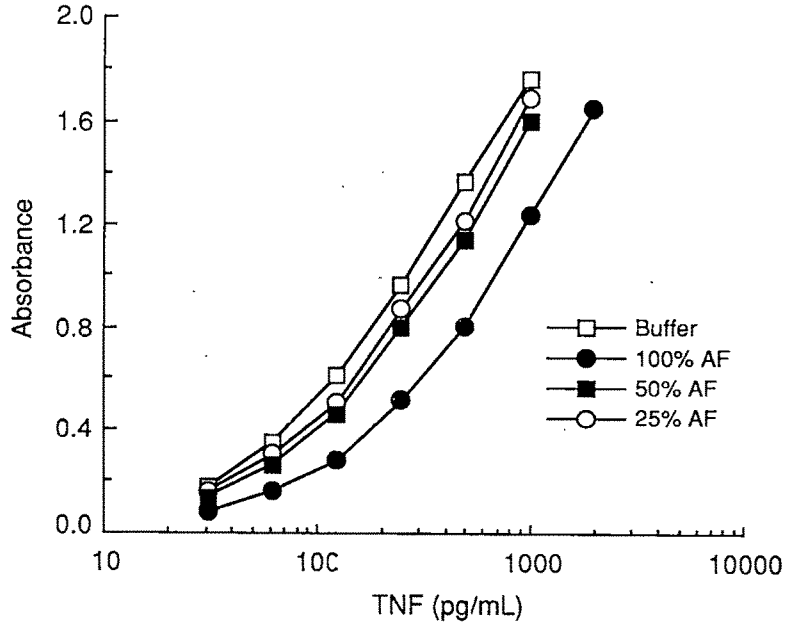

Fig. 1. Results of spike and recovery experiments. Serial twofold dilutions of recombinant human TNF-α were added to assay buffer and pooled amniotic fluid. Final concentrations of pooled fluid were 25%, 50%, and 100%. Best recovery of spiked human recombinant TNF-α was obtained when final concentration of amniotic fluid was 25%. *AF,* Amniotic fluid.

1:16	53	60	88

*Assay was performed as outlined in Material and Methods. Values displayed are the average of duplicate determinations.
†Recovery (%) = Observed value/Expected value × 100.

zyme Corporation, Cambridge, Mass.). The assay is a triple-antibody sandwich using a monoclonal anti-TNF-α antibody as the capture reagent, rabbit polyclonal anti-TNF-α, biotinylated goat antirabbit immunoglobulin with streptavidin-peroxidase, and o-phenylenediamine as the chromogen. The linear range of the assay standard curve is 25 to 400 pg/ml of TNF-α in assay wash buffer, with a detection limit of 12 pg/ml of TNF-α in assay wash buffer. The assay system has no detectable cross reactivity with ≥2 ng/ml of interleukin-1α, interleukin-1β, interleukin-2, interleukin-3, interleukin-4, interleukin-6, granulocyte-macrophage colony-stimulating factor, macrophage colony-stimulating factor, gamma interferon, and TNF-β (lymphotoxin).

ELISA validation for quantitation of TNF-α in amniotic fluid. Pooled amniotic fluid samples from normal individuals (negative bacterial culture) that did not contain detectable TNF in the L929 bioassay were used for the following validation studies:

1. Spike and recovery. Graded amounts of human recombinant TNF-α were added to 25%, 50%, and 100% amniotic fluid diluted in assay wash buffer (phosphate-buffered saline solution, Tween 20, and 0.5% protein). From these data it was determined that amniotic fluid should be diluted 1:4 to eliminate matrix effects (Fig. 1).
2. Parallelism. An amniotic fluid sample that was positive for TNF by previous ELISA assay was diluted 1:4 with wash buffer, then further diluted in wash buffer. Parallelism was determined by calculating the observed versus expected TNF concentrations (Table II).
3. The minimal detectable concentration of TNF-α was determined to be 60 pg/ml in amniotic fluid when diluted 25% with wash buffer. This value was defined as the amount of TNF-α that provided absorbance values that were 2 SDs above the mean absorbance of 10 replicate determinations of the diluent alone.
4. The coefficient of variation for intraassay precision was determined to be ≤6% by replicate determinations of six different specimens (serial dilutions from 62 to 1000 pg/ml of TNF-α diluted

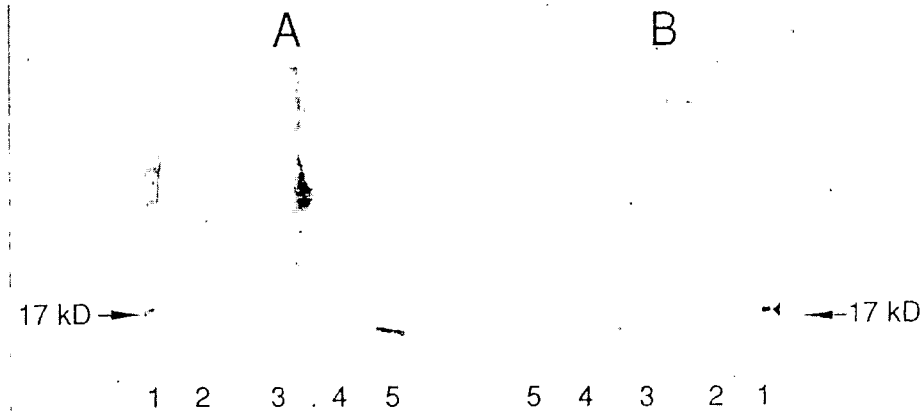

Fig. 2. Three amniotic fluid samples were assayed by immunoblot. Lanes contain: *1*, molecular weight marker; *2*, amniotic fluid containing 2000 pg/ml TNF-α (determined by ELISA) from a patient with intraamniotic infection; *3*, normal midtrimester amniotic fluid (no detectable TNF-α by ELISA); *4*, normal term amniotic fluid (no detectable TNF-α by ELISA); *5*, recombinant TNF-α. Immunoreactive bands are visible at 17 kd, which is characteristic of TNF-α, in *lanes 1* and *5* in blot *A*. Blot *A* was reacted with rabbit anti-TNF-α antiserum. In contrast, these bands are not detectable in blot *B*, which was reacted in parallel with normal rabbit serum.

in 25% amniotic fluid). Ten replicates of each specimen were tested in a single assay.

5. The coefficient of variation for interassay precision was determined to be ≤14% by replicate determinations of six different samples ranging in TNF concentration from 25 to 350 pg/ml in three individually calibrated assays.
6. The specific detection of TNF in the ELISA was confirmed by substitution of an irrelevant matched isotype (immunoglobulin G1) monoclonal (DMS-1, which binds human interleukin-2 [Genzyme Corporation]) in place of the capture reagent included in the kit. Amniotic fluid with TNF signals in the specific ELISA up to 2000 pg/ml had no detectable TNF when tested in the assay that included the irrelevant monoclonal.

Immunoblot and bioassay confirmation of TNF-α presence in amniotic fluid.

Immunoblot. Selected samples of amniotic fluid with ≥2000 pg/ml TNF-α (as determined by ELISA) were analyzed by immunoblot (WestTest Human TNF-α, Genzyme Corporation). Briefly, amniotic fluid samples were diluted 1:1 with an sodium dodecyl sulfate-2-mercaptoethanol–containing buffer and applied in duplicate wells to a 15% sodium dodecyl sulfate–polyacryamide gel. After electrophoresis, the samples were transferred to nitrocellulose in Tris-glycine buffer, pH 8.5, containing 20% methanol. The finished blot was cut in half vertically. Each half was blotted, then incubated with either rabbit polyclonal antihuman TNF-α or with preimmune rabbit serum. Both halves were then developed with protein G-biotin, streptavidin-peroxidase, and aminoethylcarbonyl chromogen. A 17 kd immunoreactive protein (Fig. 2, panel A) was detected when assayed with the relevant rabbit anti-TNF antibody. In contrast, this 17 kd protein was not detected when parallel samples were incubated with preimmune rabbit serum instead of the relevant primary anti-TNF antisera (Fig. 2, panel B).

L929 cell bioassay. The cytostatic activity of TNF-α was measured on mouse L929 fibroblasts[11] with the vital stain 3-[4,5-dimethylthiazol-2-yl]-3,5-diphenyltetrazolium bromide (MTT) (Sigma Chemical Co., St. Louis). Briefly 5×10^4 L929 cells obtained from log phase culture were added to each well of a 96-well microtiter plate, and cultured overnight at 37° C in a 5% carbon dioxide incubator. Subsequently, culture medium was removed and replaced with graded concentrations of recombinant human TNF-α (Genzyme H-TNF) (specific activity 10^7 U/mg) in complete medium, patient samples (after 1:4 dilution in complete medium and passage through a 0.2 μm sterile filter), or complete medium as a negative control. All additions contained 1 μg/ml actinomycin D (Sigma). Cultures were then incubated at 37° C in 5% carbon dioxide for 16 hours.

After the second incubation, 100 μl of culture medium was removed from each well, and 20 μl of MTT (5 mg/ml in sterile phosphate-buffered saline solution) (Sigma) was added. Cultures were incubated for an additional 4 hours at 37° C in 5% carbon dioxide, and then 120 μl of 0.4N hydrochloric acid in 2-propanol was added to each well. Cells were resuspended to dissolve MTT crystals and resultant absorbance was read at 595 nm. Bioactivity expressed by patient samples was quantified by comparison with the standard curve generated with recombinant human TNF-α.

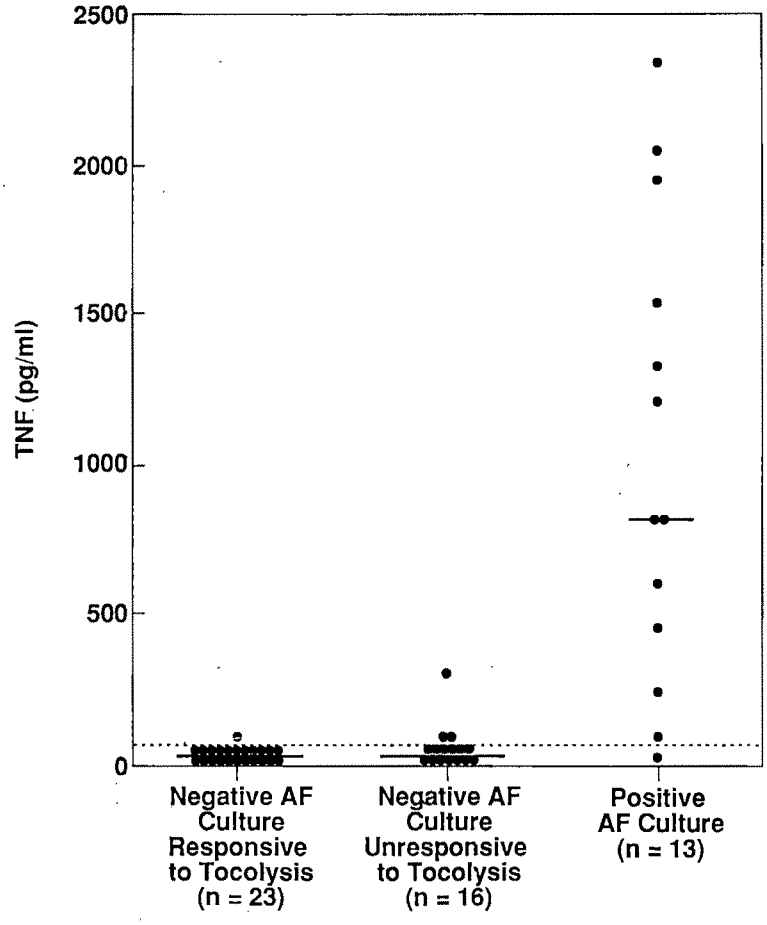

Fig. 3. Amniotic fluid TNF in women with preterm labor and intact membranes. TNF was detected more frequently in women with positive amniotic fluid culture than in women with negative culture in the other two groups ($p < 0.01$, Fisher's exact test). *AF*, Amniotic fluid.

Neutralization of TNF-α bioactivity. Specificity of cytotoxicity was confirmed with neutralizing anti-TNF antibody (IP-300, Genzyme Corporation). Selected patient samples were preincubated at 37° C with a 1:100 dilution of rabbit antihuman TNF-α antisera, whereas parallel control samples received a 1:100 dilution of normal rabbit serum. Antibody-sample mixtures were then applied to an L929 bioassay, and TNF bioactivity was determined as described.

L929 cell bioassay indicated the presence of 925 pg/ml of TNF-α bioactivity (as determined from the bioassay standard curve) in a sample that contained 865 pg/ml of TNF-α as determined in ELISA. The bioactivity in this sample was totally neutralized by pretreatment with a 1:100 dilution of rabbit anti-TNF-α neutralizing antibody (code IP-300, Genzyme Corporation). Also, both amniotic fluid samples for which TNF was undetectable in the ELISA failed to show the 17 kd band on Western blot and contained insignificant levels of cytotoxicity in the L929 bioassay.

Statistical analysis. Comparisons between proportions were performed with either a χ^2 or Fisher's exact test. An unpaired Student t test was used to compare continuous variables that were normally distributed (gestational age, maternal age). A Wilks-Shapiro test was used to test the hypothesis that amniotic fluid TNF concentrations were normally distributed. A Kruskal-Wallis analysis of variance was used to compare amniotic fluid TNF concentrations among study groups. Dunn's test was used for multiple post hoc comparisons (True Epistat, Epistat Services, Richardson, Tex.).

Results

Amniotic fluid from women in the midtrimester of pregnancy and women at term who were not in labor did not contain detectable TNF. Fig. 3 displays amniotic fluid concentrations of TNF in women in preterm labor with intact membranes. TNF was detected in 92.3% (12/13) of patients with a positive amniotic fluid culture for microorganisms (median 820 pg/ml, range <60 to 2340 pg/ml). Only three of 16 (18.7%) women in preterm labor who had negative amniotic fluid cultures for

microorganisms and premature delivery had detectable TNF in amniotic fluid. Of these patients, one had a positive amniotic fluid Gram stain for microorganisms. The second patient had a negative Gram stain but an amniotic fluid white blood cell count of 3920/mm³ with 80% granulocytes and severe histologic chorioamnionitis. There was no statistical difference in the interval between amniocentesis and delivery in patients with positive and negative amniotic fluid cultures in this group (median 6.75 hours, range 0.7 to 20 hours vs median 10 hours, range 1.5 to 21 hours, respectively; $p > 0.05$, Mann-Whitney U test). In the remaining group (negative amniotic fluid culture and delivery at term), only one patient of 23 (4.3%) had detectable TNF (100 pg/ml).

Table III displays the results of microbiologic analysis, Gram stain of amniotic fluid, histopathologic examination of the placenta, and amniotic fluid TNF concentrations of the 13 patients with a positive amniotic fluid culture. Gram stain of amniotic fluid was positive in only 61.5% (8/13) of patients. The most common microbial isolates were *Ureaplasma urealyticum* ($n = 4$), *Fusobacterium* sp. ($n = 3$), and *Gardnerella vaginalis* ($n = 3$). Polymicrobial invasion was present in 23% (3/13) of patients. None of the mothers had clinical chorioamnionitis. One newborn delivered at 26 weeks (birth weight 810 gm) had bacterial meningitis (patient 4 in Table III). Histopathologic chorioamnionitis was detectable in all patients who had positive amniotic fluid cultures and who had placental examination ($n = 8$). All these patients but one had detectable TNF in amniotic fluid. Placental examination was performed in six of 16 patients who were delivered of a preterm neonate and had a negative amniotic fluid culture. Four of these placentas (66.6%) had histologic evidence of chorioamnionitis. Only one of these patients had detectable TNF in amniotic fluid.

Fig. 4 displays amniotic fluid concentrations of TNF in women with preterm premature rupture of membranes. Women with preterm labor and positive amniotic fluid cultures had significantly higher TNF concentrations (median 249 pg/ml, range <60 to 1980 pg/ml) than did women in the other groups ($p < 0.01$). TNF was detected overall in 45.4% (15/33) of patients with a positive culture and in 2.4% (1/41) of those with a negative culture.

Table IV displays the results of microbiologic analysis, Gram stain of amniotic fluid, and amniotic fluid TNF concentrations of the 22 patients with preterm premature rupture of membranes, labor, and positive amniotic fluid culture. Table V displays similar data from 11 women with preterm premature rupture of membranes and positive amniotic fluid cultures who were not in labor. No significant difference in the proportion of women with microbial invasion exclusively caused by *Mycoplasma*, with gram-negative microorganisms or with polymicrobial infections, could be detected between the two groups. Gram stain was positive in 33.3% (11/33) of patients. Clinical chorioamnionitis was present in three patients and histologic chorioamnionitis in 16 of 20 patients in whom placental examination was performed. There were no cases of neonatal sepsis in this group.

Fig. 5 displays amniotic fluid concentrations of TNF in women at term. Overall, 25% (21/84) of women in active labor had detectable amniotic fluid TNF. Amniotic fluid TNF was detected more frequently in patients with a positive culture than in those with a negative culture (46.6% [7/15] vs 20.2% [14/69], respectively; $p = 0.047$, Fisher's exact test). Among women

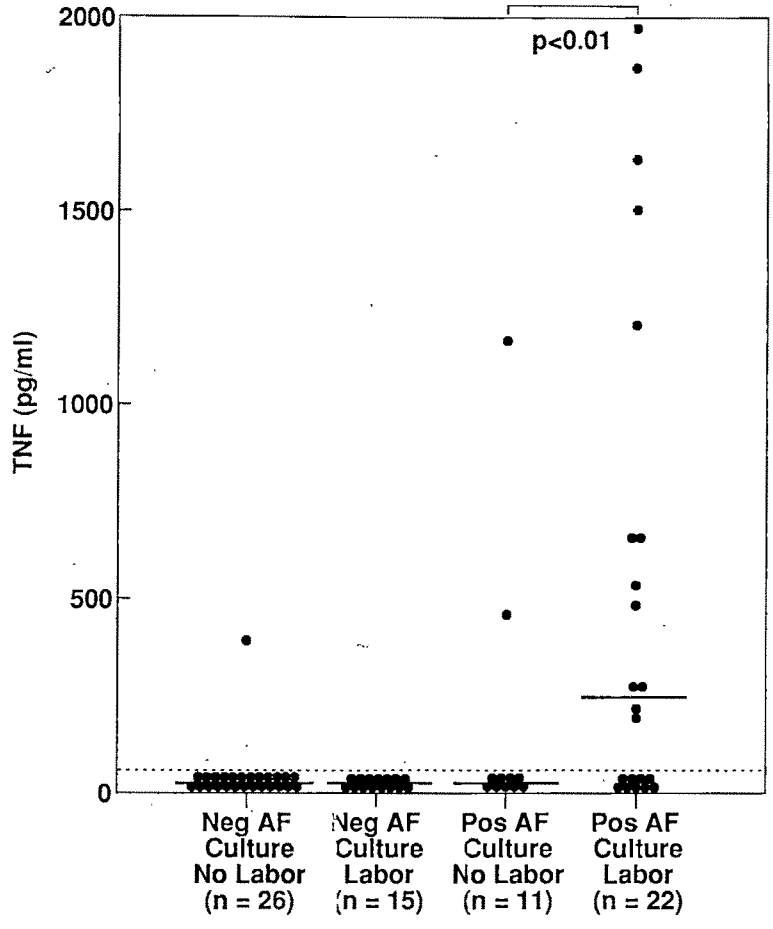

Fig. 4. Amniotic fluid TNF in women with preterm premature rupture of membranes. TNF was detected more frequently in women with positive amniotic fluid culture and preterm labor than in women in the other groups ($p < 0.001$). *AF*, Amniotic fluid.

in labor with detectable amniotic fluid TNF, those with a positive culture had a significantly higher median TNF than those with a negative culture (median 200 pg/ml, range 95 to 815 pg/ml vs median 105 pg/ml, range 60 to 660 pg/ml, respectively; $p = 0.03$, Mann-Whitney U test). Also, TNF was detected more frequently in women in labor than in women not in labor (25% [21/84] vs 0% [0/21], respectively; $p = 0.0063$, Fisher's exact test).

The most common microorganisms isolated at term were *U. urealyticum* ($n = 11$, 73.3%) followed by *Lactobacillus* sp. ($n = 2$, 13.3%). Polymicrobial invasion of the amniotic cavity was present in 20% of patients (3/15). There was no difference in cervical dilatation in patients with positive and negative amniotic fluid cultures (median 2 cm, range 0 to 6 cm vs median 2 cm, range 0 to 5 cm, respectively; $p > 0.05$, Mann-Whitney U test). Five patients had puerperal endometritis and only one of them had detectable amniotic fluid TNF. There were no cases of clinical chorioamnionitis or neonatal sepsis in this group. Placental pathologic studies were not available in these cases (probably because most newborns weighed >2800 gm and had no immediate neonatal complications).

Among women with microbial invasion of the amniotic cavity and labor, those in preterm labor had significantly higher amniotic fluid concentrations of TNF than those in term labor (median 820 pg/ml, range <60 to 2340 pg/ml vs median 47.5 pg/ml, range <60 to 815 pg/ml; $p < 0.0004$, Mann-Whitney U test) (Fig. 6).

Comment

Our data indicate that amniotic fluid from normal women does not contain detectable immunoreactive TNF. This finding is consistent with previous data generated with the use of bioassays for the detection of this cytokine.[4, 6] In contrast to other cytokines such as interleukin-6[12] and macrophage colony-stimulating factor,[13] TNF is not a normal constituent of amniotic fluid. Rather, TNF belongs to another class of cytokines (e.g., interleukin-1α and interleukin-1β), which are expressed in amniotic fluid under pathologic conditions (i.e., infection or inflammation)[2, 14] or

during certain physiologic processes such as parturition.[14, 15]

This study was designed to determine the relationship between labor and microbial invasion of the amniotic cavity and the presence of TNF in amniotic fluid. The data obtained from patients with preterm labor (irrespective of membrane status) indicate that preterm parturition in the absence of microbial invasion of the amniotic cavity is not associated with the presence of detectable TNF in the amniotic fluid; only four of 39 patients intact membranes (Fig. 3) and none of 15 patients with premature rupture of membranes (Fig. 4) had detectable TNF in the amniotic fluid. Because one of these four patients had a positive Gram stain of amniotic fluid for microorganisms and another had an amniotic fluid white blood cell count of 3920 cells/mm^3 with 80% neutrophils, the possibility must be considered that these patients had microbial invasion of the amniotic cavity that escaped microbiologic detection.

On the other hand, our data indicate that there is a strong association between the presence of TNF in amniotic fluid and microbial invasion of the amniotic cavity. In each of the three populations studied (preterm labor and intact membranes, preterm premature rupture of membranes, and term labor), TNF was detected more frequently in women with a positive amniotic fluid culture for microorganisms than in women with a negative culture. Also, in the absence of microbial invasion of the amniotic cavity, preterm premature rupture of membranes was not associated with detectable TNF in the amniotic fluid regardless of the labor status at amniocentesis (Fig. 4). However, the rate of TNF detection in the amniotic fluid of women with microbial invasion of the amniotic cavity and labor was related to gestational age and membrane status. Women with preterm labor and intact membranes had a higher rate of detectable TNF than women with preterm premature rupture of membranes in labor or women with labor at term (92.3% [12/13], 59% [13/22], and 46.6% [7/15], respectively; $p < 0.05$) (Fig. 6).

The explanation for these findings is not readily apparent. We explored the possibility that differences in qualitative microbiology might be responsible for these observations. However, the proportion of patients with polymicrobial invasion of the amniotic cavity, positive

cultures limited to *Mycoplasma* or with gram-negative microorganisms was not different among these three groups. Although it is possible that the inoculum size might be different among groups, we were unable to test this hypothesis because the majority of patients did not have quantitative microbiologic studies performed.

An alternative view is that the detection rate of TNF in amniotic fluid is dependent on the pathway of microbial invasion and the time allowed for microbial-host interaction before amniocentesis.

Although the precise origin of amniotic fluid TNF has not been determined, intraamniotic and decidual

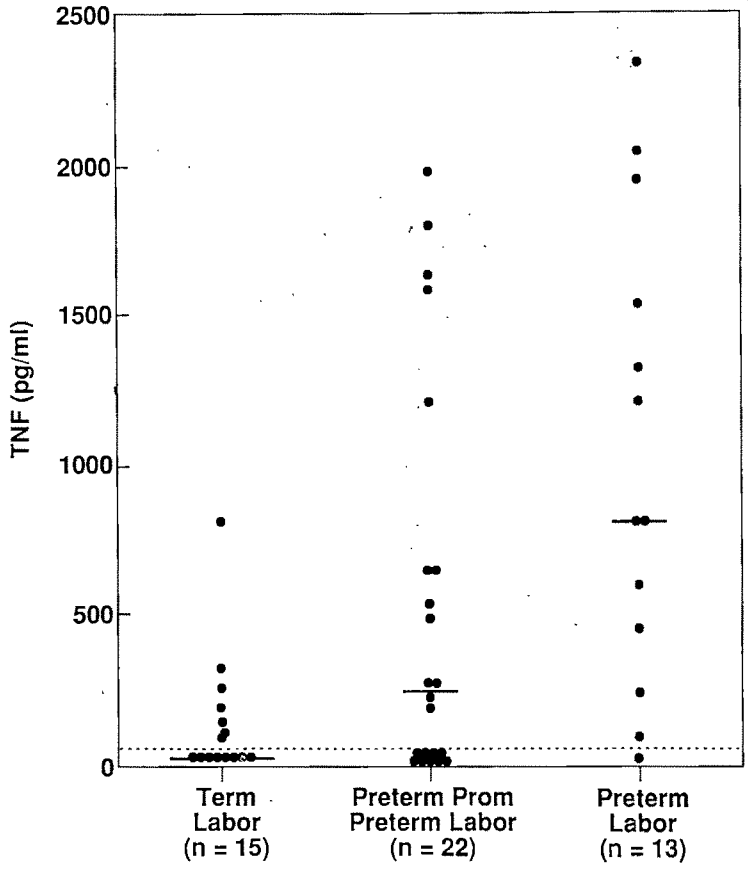

Fig. 6. Amniotic fluid TNF in women with microbial invasion of the amniotic cavity. TNF was detected more commonly in women with preterm labor and intact membranes than in women with term labor ($p < 0.05$). *Prom*, Premature rupture of membranes.

macrophages are potential sources. If the main sources are macrophages present in the amniotic cavity or fetal monocytes, the TNF concentration in amniotic fluid will be determined by factors regulating the state of monocyte or macrophage activation. Microbial invasion of the amniotic cavity of recent onset, low virulence, or limited inoculum size may lead to a modest macrophage response and TNF secretion into the amniotic fluid. This is the likely course of events associated with microbial invasion of the amniotic cavity that occurs in the context of spontaneous labor at term. In contrast, if microbial invasion of the amniotic cavity is of longer duration, of high virulence, or due to large inoculum size, macrophage activation will be more intense and amniotic fluid cytokine (including TNF) concentrations will be higher. This is the most likely course of events in cases of preterm labor associated with microbial invasion of the amniotic cavity. Another potential source of amniotic fluid TNF is decidual macrophages, which constitute approximately 30% of the total cell population of the decidua. However, we have no direct evidence, at this point, that TNF produced by the decidua can cross intact membranes into the amniotic cavity.

The role of decidual cytokine production in mediating parturition in the setting of infection probably varies with gestational age. In term pregnancy, mild decidual disruption such as that caused by stripping of the membranes or by a localized extraamniotic infection (deciduitis) may be sufficient to activate decidual macrophages to produce cytokines, stimulate myometrial contractility, and signal the onset of labor. In contrast, the magnitude of the stimuli (pharmacologic, mechanical, infectious-related) required to elicit parturition in early pregnancy seems to be considerably greater. This uterine unresponsiveness has probably evolved to protect against premature birth. Thus the earlier the gestation, the less likely that an extraamniotic infection by itself will be sufficient to signal parturition. In the absence of labor, microorganisms that have gained access to the decidua continue to proliferate, cross intact membranes, and then stimulate resident macrophages and other host cells (including fetal cells) to produce cytokines from within the amniotic cavity. This additional set of signals (to those generated during decidual infection) may then lead to parturition. If they do not, microorganisms may gain access to the fetus, activate fetal immunocompetent cells to produce cytokines, and elicit the endocrine changes associated with infection and parturition.

A puzzling finding in our study is that 20% of women in active labor at term with a negative amniotic fluid culture had detectable TNF in the amniotic fluid. Sev-

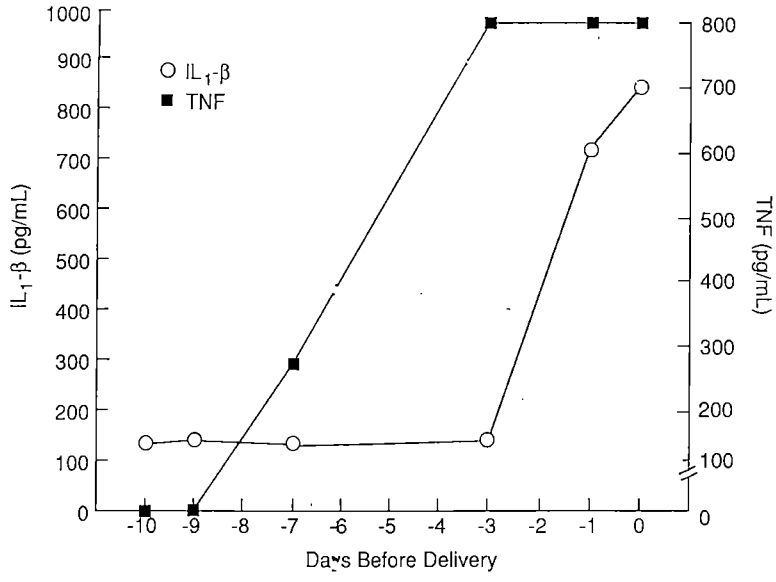

Fig. 7. Longitudinal observation of amniotic fluid TNF and interleukin-1β concentrations in patient in preterm labor with intact membranes and positive amniotic fluid culture.

eral explanations for this finding may be invoked. First, these patients may have had false-negative microbiologic studies. If this were the case, however, we would have to accept a rate of subclinical colonization of the amniotic cavity of 25% in term spontaneous labor. This estimate is higher than that reported by the only study using amniocentesis for collection of fluid in women in term labor.[16] An alternative view is that tissue disruption associated with parturition may lead to macrophage activation and the secretion of TNF in the amniotic cavity. This implies that a state of noninfectious macrophage activation may exist in some women with term spontaneous parturition. We have recently demonstrated that spontaneous parturition at term in the absence of demonstrable infection is associated with an elevation of amniotic fluid interleukin-6 levels.[12, 17] Because interleukin-6 can induce TNF gene expression by macrophages,[18] TNF detection in the amniotic cavity may be the consequence of activation of the cytokine network through a noninfectious mechanism. Further studies are required to clarify these issues. In situ hybridization analysis for cells containing TNF messenger ribonucleic acid and immunohistochemical localization of TNF protein in tissue sections are procedures currently available to address questions concerning the sources of amniotic fluid TNF and the relationship between inflammation, infection, parturition, and TNF expression.

Because TNF is capable of stimulating prostaglandin production by amnion[4] and decidua,[5, 6] we have proposed that this cytokine may participate in the signaling process responsible for the initiation of labor in the setting of infection.[4] Observations made in the current study of women with preterm premature rupture of membranes support this view. Indeed, the detection rate of TNF in amniotic fluid was greater in women with preterm labor and microbial invasion of the amniotic cavity than in women with microbial invasion but without preterm labor. These data indicate that parturition in the setting of infection is temporally associated with the secretion of TNF into the amniotic cavity and support the view that the initiation of parturition may be viewed as part of the repertoire of host-defense mechanisms elicited in response to intrauterine infection.

Further clinical support for this hypothesis is derived from longitudinal observations made in a patient in preterm labor (Fig. 7). This patient, admitted with preterm labor and intact membranes, had a positive amniotic fluid culture for *Candida* sp. The final episode of preterm labor and delivery, which occurred 11 days after admission, was preceded by the subsequent detection of amniotic fluid TNF and its increased concentrations in the amniotic cavity.

If preterm labor in the setting of infection is mediated by cytokines, including TNF, why then do 40.9% of women with preterm premature rupture of membranes and labor and a positive amniotic fluid culture not have detectable TNF? One possibility is that TNF is not required in all patients with infection to signal the onset of labor. Other members of the cytokine network, such as interleukin-1, may have a more critical role. Further studies in which several cytokines are assayed in the same sample are required to address this issue. Another possibility is that microbial invasion of the amniotic cavity in these patients occurred during the course of labor and that the mechanisms for initiation of parturition are unrelated to infection and cytokine. In these instances infection is the consequence rather than the cause of labor.

Can the assay of amniotic fluid TNF have clinical value? Although the current study was not specifically designed to address this question, the data from patients in preterm labor with intact membranes indicate that the detection of TNF in amniotic fluid in this population had a greater sensitivity than did the Gram stain in the diagnosis of microbial invasion of the amniotic cavity (sensitivity 92.3% [12/13] vs 61.5% [8/13], $p = 0.16$; specificity 89.7% [35/39] vs 97.4% [38/39], $p = 0.35$). Moreover, the presence of TNF in the amniotic fluid might identify a group of patients at risk for preterm delivery in spite of tocolytic treatment. Only one of the seven patients (14.2%) with detectable TNF and a negative Gram stain of amniotic fluid was delivered at term. It should be noted that this performance of amniotic fluid TNF determinations was not maintained in women with preterm premature rupture of membranes (TNF sensitivity 45.4% [15/33] and Gram stain sensitivity 33.3% [11/33], $p = 0.2$). If this observation is confirmed, the utility of TNF determinations in the diagnosis of microbial invasion of the amniotic cavity in patients with preterm premature rupture of membranes would be limited.

The use of cytokine determinations in the diagnosis of infection depends on the magnitude of the host response and not merely on the presence of microorganisms. This apparent limitation, however, could be exploited in clinical obstetrics. The combined use of modern microbiologic techniques (e.g., polymerase chain reaction) and cytokine determinations may identify the patient in whom microbial invasion is recent enough as to not have elicited a host response (i.e., cytokine secretion). This patient is likely to be the one who benefits the most from antibiotic treatment. Indeed, our data indicate that once microbial invasion of the amniotic cavity is accompanied by a robust cytokine secretion into the amniotic fluid, delivery is inevitable.

LETTERS TO THE EDITORS

Magnesium sulfate is an unfit anticonvulsant in eclampsia

To the Editors: I read with great interest the article of Sibai (Sibai BM. Magnesium sulfate is the ideal anticonvulsant in preeclampsia-eclampsia. AM J OBSTET GYNECOL 1990;162:1141-5). As Sibai pointed out, magnesium sulfate has been recommended in the treatment of eclampsia; however, comprehensive data regarding its reliance and safety are lacking. I believe that patients will not be injured by the drug if the principles of treatment are followed.

There are multiple actions of magnesium sulfate that may be useful or nonhelpful to the fetus and mother. Effects on fetal heart variability and associated low Apgar scores, respiratory depression, hyporeflexia, and hypocalcemia have been reported in the neonates of mothers receiving intravenous magnesium sulfate. These effects were reported in premature infants in association with fetal growth retardation. Such complications may be present in these infants whether magnesium sulfate is or is not used. The perinatal mortality rate was reported to be as much as 17.1%[1] and 45%[2] when magnesium sulfate was used. Our hospital has not used magnesium sulfate, and the perinatal mortality rate is 2.78% (3/108).[3] In contrast, the maternal mortality rate in other large series of patients with eclampsia ranged between 3.3% and 14.4%, and the incidence of intracerebral hemorrhage was as high as 10.7% (Sibai's article). Dr. Sibai's patient was resuscitated and her seizures were controlled with magnesium sulfate. In our hospital taking care of patients with eclampsia without the use of magnesium sulfate has resulted in a maternal mortality of zero (0/106).[3]

Parenteral magnesium sulfate is the drug of choice to prevent convulsions in cases of eclampsia, but it is not suitable as an anticonvulsant in eclampsia. Magnesium sulfate controls convulsions of eclampsia but seriously endangers the health of both the mother and her fetus. We consider magnesium sulfate to be dangerous in our hospital; hence, it is not used.

Reply

To the Editors: I do appreciate the interest of Dr. Luan in the subject of eclampsia and magnesium sulfate. Dr. Luan cites some statements from *my* manuscript without indicating the purpose or reason for including them, which makes it difficult to respond to his letter. He then cites a perinatal mortality rate of 2.78% in his experience with eclampsia as an indication not to use magnesium sulfate. He compares it to previous perinatal mortality reported in 1959 (his reference 2) and in 1979 (his reference 1). Again, I fail to see the association since he does not explain what is meant by perinatal mortality. Did he include patients who had stillbirths or neonatal deaths before arrival to the hospital? What are the gestational ages? Did he include patients with gestational ages <28 weeks? Currently, neonatal survival for infants >28 weeks' gestation is almost 100% in Memphis. This has nothing to do with magnesium sulfate. In addition, neonatal survival for preterm babies in Memphis is definitely superior to that in China. He also mentions maternal mortality without use of magnesium sulfate. Again, he does not mention the condition of the patient on admission and how many were excluded before admission.

Finally, he concludes that magnesium sulfate is an unfit anticonvulsant in eclampsia. It is surprising for someone who has never used the drug to make such a statement. In addition, he does not report what drug he uses. It is ridiculous to make such statements without data to support them.

The issue of animal rights and human rights

To the Editors: I agree with much of what Mister Maharry (Maharry TM. The issue of animal rights and human rights. AM J OBSTET GYNECOL 1991;164:1543-8) says about medical research being dependent on animal experimentation. I support the use of animals in appropriately screened experiments. I am also a member of the Physicians Committee for Responsible Medicine, and I believe that there are substantial experiments going on in this country that use animals. A number of these experiments are superfluous or do not particularly further the cause of medical knowledge. I believe this type of experiment still needs to be weeded out. Although some animal activist groups have been violent, I believe that in general the cause for protection against cruelty to animals has been advanced. We have all become more sensitive to the injustices that humans have dealt the animal world.

I cannot deny that violence is not an appropriate response, but as an animal rights advocate I believe closer scrutiny of the use of animals in experimentation and closer scrutiny of the usefulness of the experiments themselves is an appropriate response. Do not lump all animal rights activists with the few violent ones. We need to take a close look at our respect for the animal kingdom. Many species have been destroyed through

our carelessness. Perhaps being made more sensitive to their plight will benefit humankind in a way more significant than it may seem at face value. Food for the hungry is important, but survival of the planet to feed all of us is most important.

Fetal biophysical and umbilical cord gases

To the Editors: The article by Vintzileos et al. (Vintzileos AM, Fleming AD, Scorza WE, et al. relationship between fetal biophysical activities and umbilical cord blood gas values Am Obstet Gynecol 1991;165:707-13) is an important contribution to our understanding of some aspects of fetal pathophysiology and its detection before significant morbidity or fetal death. I have some observations about this paper.

First, the title of Table VI should be Umbilical venous blood rather tham Umbilical artery blood.

Second, the authors did not comment on the influence, if any, of the maternal oxygen administration rate of 3 L/min on umbilical cord venous and artery Po_2. In spite of maternal oxygen administration the values of umbilical venous and artery Po_2 with reactive nonstress test and fetal breathing movements present appear to be low. Would a contraction stress test have been more useful in identifying impending fetal-neonatal morbidity at a higher value of venous and artery Po_2?

Third, it is not surprising to note that fetal hypercapnia occurred only when fetal movement and tone were absent and was associated with significant fetal acidosis and hypoxia. This occurrence is explained by the physiologic fact that Co_2 exchange across placenta membranes or alveoli is much more efficient than the exchange of oxygen.

Houchang Modanlou, MD
2801 Atlantic Ave., P.O. Box 1428, Long Beach, CA 90801-1428

Reply

To the Editors: We thank Modanlou for his interest in our work. We agree with his first comment that the title of Table VI should be umbilical venous blood rather than umbilical artery blood.

In our opinion the relatively low umbilical cord venous and artery Po_2 in spite of maternal oxygen administration of 3 L/min was related to the fact that the oxygen administration was of very short duration. This time period was from satisfactory epidural analgesia (when skin incision was made) until delivery of the infant. However, the main emphasis of our study was to investigate the relationship between the presence or absence of the individual fetal biophysical activities and umbilical cord blood gas measurements and to compare the different levels of pH, Po_2, Pco_2, and bicarbonate and base excess at which the individual biophysical activities become compromised. We did not attempt to establish normal umbilical cord venous and artery Po_2 values. Therefore for reasons of comparison the absolute Po_2 levels were not important because all patients received epidural analgesia and had the same degree of maternal oxygenation. We doubt that a contraction stress test could be useful in identifying impending fetal-neonatal morbidity. In general the appearance of late decelerations of the fetal heart rate in response to uterine contractions may suggest fetal hypoxia caused by uteroplacental insufficiency. However, this concept is valid only during the intrapartum period because the frequency and intensity of the uterine contractions can be monitored with internal monitoring techniques. External monitoring techniques like those used in the antepartum contraction stress test, however, are not capable of measuring the intensity of the uterine contractions and therefore the strength of the stimulus to the fetus. In our opinion any judgment about the presence or absence of fetal hypoxia when the intensity of the stress factor (uterine activity) is unknown is not reasonable and has no scientific basis.

We agree with Modanlou's comment that carbon dioxide exchange across placental membranes is much more efficient that oxygen exchange. We also believe that fetal hypercapnia in the absence of fetal movement and tone may also be related to umbilical cord compression, as is frequently seen in cases in which oligohydramnios is associated with intrauterine growth retardation and compromised biophysical activities.

Hemolytic disease of the fetus

To the Editors: Weiner et al. (Weiner CP, Williamson RA, Wenstrom KD, et al. Management of fetal hemolytic disease by cordocentesis. I. Prediction of fetal anemia. Am J Obstet Gynecol 1991;165:546-53) report a management scheme for hemolytic disease of the fetus based on results from cordocentesis. Although the authors stop short of recommending the abandonment of amniocentesis, it is clear that in their unit they have. Although their results were good, there was no prospective comparison to an amniocentesis-based management scheme. Unfortunately, the authors (and readers) can only speculate on the broad range of relative advantages and disadvantages of each scheme.

My questions regard the selection of patients for invasive testing. The authors state that an indirect Coombs' titer of $\geq$1:8 was selected for testing because in their unit severe hemolytic disease has occurred at 1:8 but not below. This same threshold was reported by Reece et al.[1]; it places the critical titer for their laboratories at 1:4, which is one dilution stricter than that recommended by the American College of Obstetricians and Gynecologists Technical Bulletin[2] (>1:8) and two dilutions stricter than the data-based recommen-

dations of Freda[3] and Queenan[4] (>1:16). As a consequence of this stricter critical titer, more patients require invasive testing or require it earlier in pregnancy.

My questions: (1) In their current series, in a first sensitized pregnancy what was the lowest fetal hematocrit observed when the indirect Coombs' titer within 1 to 2 weeks of sampling was ≤1:16? (2) Do the observations in the current series justify invasive sampling in the first sensitized pregnancy when a recent indirect Coombs' titer is 1:8 or 1:16? (3) Can their historic observation of severe fetal hemolytic disease with a titer of 1:8 be explained by (a) its occurrence in an other-than-first sensitized pregnancy, (b) delivery remote from the 1:8 titer with possible intervening unobserved increases in titer, or (c) an unobserved increase in titer caused by invasive sampling after the titer? MacGregor et al.[5] reported a rise from 1:8 to 1:4096 within weeks of cordocentesis.

If the answers to these questions do not support invasive testing in first sensitized pregnancies with 1:8 or 1:16 titers, the authors should acknowledge this and adjust their critical titer. This adjustment would allow the selection of invasive testing only when the fetal risk truly warrants it.

Reply

To the Editors: We thank Spinnato for his inquiry. We expect may questions will arise regarding the proposed management scheme because it is difficult to give adequate detail in an initial publication.

Spinnato asked about the antibody titer at which an invasive evaluation should be undertaken during the first sensitized pregnancy. His specific concern was that we selected 1:8 although the American College of Obstetricians and Gynecologists Technical Bulletin states that a titer of <1:16 indicates that the fetus is not in serious jeopardy. His question is best answered by quoting directly from that technical bulletin. "In general, it is believed that, if the antibody titers remain less than 1:16 in an initial immunized gestation, the fetus is not in serious jeopardy. *It is important to know, however, that this value is somewhat dependent on local laboratory methods, skill of laboratory personnel, and previous experiences related to titers within that institution* [emphasis added]."

Spinnato is not the first to have missed this point. With the decreasing incidence of fetal hemolytic disease, experience with the entity has shrunk. Our critical titer has been and remains 1:8 and is the result of many years of experience in one laboratory with a wide referral area. All physicians involved in the evaluation of fetal hemolytic disease should find the critical titer in their individual laboratories. Obviously this is impossible in a small hospital; regionalization is required.

In our experience patients have frequently been referred with a low indirect Coombs' titer from the local laboratory, only to have a much higher titer when tested by the University of Iowa Hospitals and Clinics blood bank. Whether this reflects a change in sensitization or differences in laboratories, I cannot state.

Our data base does not include information as to whether the pregnancy under evaluation was the first sensitized pregnancy. As a rule we monitored each patient during her first sensitized pregnancy with serial indirect Coombs' titers. We require a titer ≥1:8. Ten nulliparous women have undergone cordocentesis for red blood cell isoimmunization. Two of those fetuses had anemia when first evaluated. In one, sensitization was to D and the indirect Coombs' titer was 1:1024. In the other, sensitization was to Kell and the indirect Coombs' titer was 1:8. However, most of the patients who have required transfusion with low indirect Coombs' titers were not in their first sensitized pregnancies. Thus our observation of severe hemolytic disease with a titer of 1:8 is mostly, but not exclusively, explained by its occurrence in a subsequent sensitized pregnancy. As Spinnato notes, other have had similar experiences with their laboratories.

Spinnato refers to a case report by MacGregor et al., who observed an abrupt increase in antibody titer within weeks of cordocentesis. However, I note that the fetus in question was already anemic when the titer was 1:8. This raises an important point. Cordocentesis is but a procedure. One must not only know what the normal values are, but what to do with them. With our management scheme we have tried to supply a course of action. The procedure can also be misused. To prevent worsening of disease we avoid the placenta in patients with low-grade sensitization by sampling from a midsegment.

In summary, the 1:16 guideline in the American College of Obstetricians and Gynecologists Technical Bulletin was never intended to be engraved in stone. It is clear that at the University of Iowa our critical titer is 1:8. Our experience is that these fetuses are at risk and benefit from accurate testing.

Ultrasonographic screening for trisomy 21

To the Editors: In the article by Lockwood et al. (Lockwood CJ, Lynch L, Berkowitz RL. Ultrasonographic screening for the Down syndrome fetus. AM J OBSTET GYNECOL 1991;165:349-52) the authors estimate the positive predictive value for Down syndrome of both the biparietal diameter/femur length ratio and measured femur length/expected femur length ratio for a given biparietal diameter. To calculate this predictive value they used a prevalance of Down syndrome (1/710) that reflects the incidence of Down syndrome at 16 weeks' gestation for the general population. An alternative estimate of the prevalence in a target population might include all pregnancies in women <35 years of age and 50% of woman >34 years who do not have amniocentesis. This formula would lower the prevalence (assuming there are 4.2 million live births per year[1], that 8.6% of live births occur to women >34 years of age, that 39% of Down syndrome births occur in women >34 years,[2] and that Down syndrome occurs in 1/1000 live births) to 1/884 at 16 weeks and reduce the positive predictive value to below the levels cited by approximately 20% to 30%.

Additionally, there appears to be an error in the estimate of predictive value for study 9 in Table I. The correct positive predictive value should be 1/108 rather than 1/644.

Reply

To the Editors: We thank Bernstein for his analysis of the positive predictive value of the various biparietal diameter/femur length formulas for detecting fetal Down syndrome. He is correct in his analysis of this alternate approach to the estimation of positive predictive values. In addition, he rightly points out a typographic error in study 9. The positive predictive value of this study is indeed 1/108 rather than 1/644.

What is the prognosis for congenital cytomegalovirus infection?

To the Editors: We read with interest the article by Lynch et al. (Lynch L, Daffos F, Emanuel D, et al. Prenatal diagnosis of fetal cytomegalovirus infection. AM J OBSTET GYNECOL 1991;165:714-8). This article demonstrates the usefulness of a comprehensive evaluation of fetuses with possible congenital cytmegalovirus infection. Although the numbers are small (6 of 7), it appears that women who have a documented primary infection during pregnancy can be reassured if their fetus has normal blood studies, normal ultrasonographic findings, and a negative amniotic fluid culture.

Although we agree that the prognosis is likely to be poor for congenitally infected infants who are detected solely on the basis of abnormal ultrasonographic findings, this is not certain. There has been at least one case in which ascites diagnosed at 27 weeks' gestation completely resolved before birth at 36 weeks' gestation.[1] This infant had minimal findings at birth.

The natural history of congenital cytomegalovirus infection is still not known in detail. We agree that more long-term follow-up of fetuses and neonates known to be infected in utero is needed.

Omental graft made simple

To the Editors: Since my article (Petty WM, Lowy RO, Oyama AA. Total abdominal hysterectomy after radiation therapy for cervical cancer: use of omental graft for fistula prevention. AM J OBSTET GYNECOL 1986;154:1222-6) was published, it has been found that it is not usually necessary to make a pedicle graft of the omentum to attach it to the vagina. Normally the omentum is long enough to reach the vaginal apex without being on tension. If the omentum will reach the vaginal apex without being on tension, it can be gently sutured to the vaginal apex with two interrupted absorbable sutures after the vagina is closed. I have only had to make a pedicle graft once in approximately 12 additional cases. The other 11 times the omentum has reached the vagina without being on tension. Therefore a simplified method of preventing fistulas after either full radiation therapy or a partial radiation therapy with hysterectomy is to simply suture the distal omentum to the vaginal apex. It is quick, easy, takes only 2 minutes, and has completely prevented fistulas in my patients.

Ovarian cancer screening

To the Editors: The issue of screening for ovarian cancer is a timely one: it is of particular concern not only to

gynecologists and other primary care physicians, but also to imaging specialists. It is unfortunate, therefore, that in the otherwise excellent review of this topic by Creasman and DiSaia (Creasman WT, DiSaia PJ. Screening in ovarian cancer. AM J OBSTET GYNECOL 1991;165:7-10) the authors based their opinion of ultrasonography as a screening technique on three ultrasonography articles from 1988 and 1989 (reflecting the standard of imaging of the years preceding publication). None of the referenced articles included transvaginal evaluation of the ovaries or Doppler visualization of the supplying ovarian and uterine arteries. This omission is particularly distressing in that the same issue of the journal that contained the ultrasonography article by Campbell et al.[1] also contained another paper[2] in which that group reported their early and encouraging results with the use of transvaginal color flow imaging to identify malignant ovarian masses.

Since that time multiple papers have appeared on the use of transvaginal evaluation of ovarian masses and the characterization of the blood flow by Doppler technique. Our own recently published work[3] has demonstrated the use of transvaginal ultrasonography in identifying very small, nonpalpable masses in asymptomatic postmenopausal women.

Because of the tremendous advances that have been made in ultrasonographic technology within the past 2 years, I believe that basing such an important conclusion on outmoded technology is a disservice not only to your readers, but also to the millions of women who are concerned about their risk for ovarian carcinoma. There is no doubt that a large multicenter study is needed to evaluate the use of modern diagnostic ultrasonography in the identification of early ovarian carcinoma. Campbell and Bourne and their colleagues have made a good start. Meanwhile it is counterproductive to deny our patients such a valuable imaging study while waiting the 5 to 10 years it will take for final results.

Barbara B. Gosink, MD

Department of Radiology, University of California, San Diego, Medical Center, 225 Dickinson St., San Diego, CA 92103-1990

REFERENCES

3. Wolf SI, Gosink BB, Feldesman MR, et al. Prevalence of simple adnexal cysts in postmenopausal women. Radiology 1991;180:65-71.

Reply

To the Editors: We appreciate Gosink's interest in our article. Her main criticism is that we quoted studies using supposedly antiguated technology (abdominal ultrasonography). The studies we referenced were published in 1988 and 1989—not necessarily ancient history. We are well aware of transvaginal ultrasonography and color flow Doppler. The ability of transvaginal ultrasonography in regard to sensitivity in identifying ovarian follicles is well established with the in vitro fertilization programs. We chose those articles because they were by far the best and largest studies published. There are no like published articles with transvaginal ultrasonography as a screening tool for ultrasonography! Gosink noted that Campbell et al. had published an article on color flow Doppler and wondered why it was not referenced in our publication. That study is a presentation of 50 *selected* patients and does not represent a technique or data on screening for ovarian cancer.

Gosink suggested that transvaginal ultrasonography is better technology than abdominal ultrasonography and quoted one of their own articles. In their article both abdominal and transvaginal ultrasonography were used in 149 patients. They actually identified more ovaries with the abdominal ultrasonography than the transvaginal method (58% vs ≤1%). In fact, they were unable to identify 32% of the ovaries known to be present with either technique. Their inference was that if they did not see the ovaries, cysts were probably not present (the main thrust of their paper was the identification of "cysts" in a postmenopausal patient). On the other hand, Campbell has made the point that it is necessary to identify the ovary to state that no pathologic condition is present (their report was based on over 30,000 ovaries). Gosink stated that 30 minutes was the usual time for ultrasonographic evaluation, with the radiologist involved some of the time. We wonder what the cost would be if this were not a study?

One of the points in our article was that the incidence of ovarian cancer (approximately 20,000 per year) is relatively low, particularly when compared with other cancers (breast—approximately 175,000 per year); therefore any screening test is probably not going to be effective in making a major impact on the dismal survival rate for this cancer. As noted from the paper by Einhorn et al.[1] quoted in our article, the CA 125 test was used as a screening test. Einhorn et al. stated that considering the incidence of ovarian cancer in Sweden, even if the test had a specificity of 99.5%, only 6% to 11% patients with elevated CA 125 levels would actually be expected to have cancer even if the sensitivity was 100%. In Campbell's study, for every 67 patients coming to surgery because of abnormality noted on ultrasonography examination, only 1 was expected to have a primary ovarian cancer, obviously a very high false-positive rate. After their large study with over 30,000 ovaries evaluated, Campbell et al. have stated that the cost-effectiveness of ultrasonography must now be determined. There are several ongoing studies evaluating this technique alone and with tumor markers. Even if transvaginal is proved to be better than abdominal

(which it has not), is it still cost-effective as a screening technique?

To the statement that new technology makes previous data (abdominal ultrasonography) no longer applicable, we argue that it is not appropriate to accept new technology carte blanche without data supporting its effectiveness. Even if transvaginal ultrasonography were 100% sensitive and specific, an accuracy rate no one suggests, there would still be major problems because of the numbers. To take new technology without proving its effectiveness as state of the art may add tremendous expense to already massive health care costs without decreasing the mortality of this cancer and is a disservice to our patients and medicine in general.

Epidermal growth factor receptor expression in cervical intraepithelial neoplasia

To the Editors: I read with interest a recent article by McGlennen et al. (McGlennen RC, Ostrow RS, Carson LF, Stanley MS, Faras AJ. Expression of cytokine receptors and markers of differentiation in human papillomavirus–infected cervical tissues. AM J OBSTET GYNECOL 1991;165:696-705). The authors found increased levels of epidermal growth factor receptor with increasing levels of cervical dysplasia. In our study[1] we found levels of expression of messenger ribonucleic acid for epidermal growth factor receptor to correlate with levels of cervical dysplasia, with expression of epidermal growth factor receptor messenger ribonucleic acid in basal and parabasal epithelium in normal cervix, and up to and above midepithelium in moderate and severe dysplasia. Presence of messenger ribonucleic acid for epidermal growth factor receptor suggests not only presence but continued synthesis of epidermal growth factor receptor in dysplastic cells. The study by McGlennen et al. shows actual increase in the amount of epidermal growth factor receptor with increasing severity of dysplasia, a finding that further supports a role for epidermal growth factor receptor in the pathogenesis of cervical dysplasia.

Fig. 3 and its legend in the article by McGlennen et al. are mislabeled as showing *EGF* (epidermal growth factor) instead of *EGFR* (epidermal growth factor receptor).

Perinatologist Needed in Coastal New Jersey

2 member group is seeking a third perinatologist (BE/BC). We are active practitioners of perinatology and we also serve as integral members of the teaching team for a residency in Obstetrics and Gynecology.

We engage in both in-patient and out-patient activities, and all skills related to maternal fetal medicine may be used within our practice. Strong ultrasound skills are required, and the current practice consists of antenatal diagnosis, genetic counseling, amniocentesis, CVS and PUBS. We will insist on comfort and competence in basic obstetrical practice.

We are located about 1.5 hours from both New York City and Philadelphia, and the area provides a suburban life style.

Fax: (908) 870-0119

MATERNAL/FETAL SUBSPECIALISTS
EASTERN PENNSYLVANIA

Lehigh Valley Hospital, an 830-bed tertiary care teaching hospital, is seeking additional faculty including two full-time maternal/fetal medicine subspecialists: a division chief and an associate. The physicians' roles will include consultative patient care, program development, student and resident education and research if desired. The opportunity exists to customize the role to your particular career goals. Candidates should be board certified or active candidates for certification in maternal/fetal medicine.

Lehigh Valley Hospital is a regional Perinatal Center with over 3,300 births annually, of which 40 percent are high-risk. The department is supported by a 20-bed Level III NICU and four full-time neonatologists. The hospital serves as a clinical campus of Hahnemann University and maintains a free-standing, fully-accredited OB/GYN residency program.

Allentown, Pennsylvania is a cosmopolitan city, 60 miles north of Philadelphia and 80 miles west of New York City. The area has excellent school systems, nine colleges and universities and diverse cultural offerings. An excellent compensation package has been designed to recruit qualified candidates. Please send CV to **Carol Voorhees, Vice President, Lehigh Valley Hospital, 1243 S. Cedar Crest Boulevard, Suite A, Allentown, PA 18103, or call (215) 821-3090.** EOE.

PERINATOLOGIST
OGDEN, UTAH

An outstanding opportunity exists for a perinatologist to set up a consultative practice in Ogden, Utah. The physician will be an employee of McKay-Dee Hospital, a 415-bec community facility. Office space, personnel and equipment will be provided by the hospital. The successful candidate will be an integral part of Intermountain Health Care's Perinatal Group.

Ogden, Utah is a beautiful community of 69,000, with a service population of 260,000. There is an abundance of outdoor recreation available, including skiing, snowmobiling, hunting, fishing, boating, swimming and camping. A variety of cultural events entertain and amuse Ogden residents, such as the symphony, the ballet, museums, art galleries and festivals. Ogden is a short 40 minutes from Salt Lake City where more professional sports and cultural events may be found.

MATERNAL/FETAL SPECIALIST AND OBSTETRICIAN/GYNECOLOGIST

A renowned regional medical center in southwestern Virginia has two faculty positions available for an OB/GYN and a MATERNAL/FETAL specialist. Selected candidate can expect a strong compensation package and excellent benefits. located near the Blue Ridge Parkway, this All-American City of 250k combines a mix of rural beauty with an urban lifestyle. Call Sandy Cundiff at 800 683-0259 or FAX C.V. to The Paxton Group at 804 626-0651.

21- and 28-day regimens

ORTHO-NOVUM 777 Tablets

TRADE MARK

norethindrone/ethinyl estradiol

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert.**

ADVERSE REACTIONS: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiform. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis.

OVERDOSAGE: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

FEMSTAT® PREFILL
(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

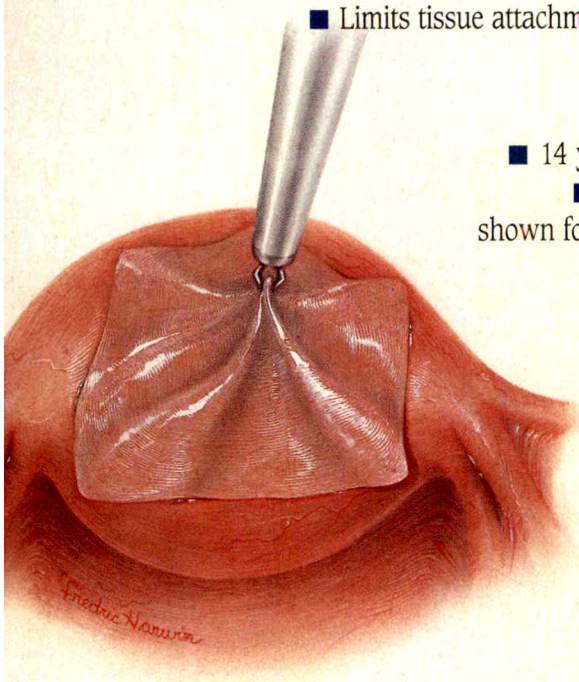
nvariant Performance in Peritoneal Reconstruction of Myomectomy Sites



.The GORE-TEX® Surgical Membrane
he Choice in Peritoneal Reconstruction

Incision sites for myomectomy can be a significant post-operative problem. Hemostatically difficult to control, they demand an adjuvant unaffected by the biological processes that occur following deperitonealization...The GORE-TEX Surgical Membrane.

Performance by Design

- Composed of the inert biomaterial, expanded polytetrafluoroethylene (e-PTFE)
- Limits tissue attachment with an extremely small pore size

Proven and Established

- Long record of safety and effectiveness
- 14 years of reliability demonstrated among cardiac surgeons
- Safety substantiated and invariant performance shown for myomectomy site protection in a multi-center clinical study

Convenient

- Configured for Peritoneal Reconstruction
- Packaged sterile and **can be resterilized**

To receive further information on the GORE-TEX Surgical Membrane or to consult an application specialist, call **1-800-437-8181**. For orders and overnight delivery, 24 hours a day, please call **1-800-528-8763**.

TRANSACTIONS OF THE FIFTY-EIGHTH ANNUAL MEETING OF THE PACIFIC COAST OBSTETRICAL AND GYNECOLOGICAL SOCIETY

Folly, woodenheadedness, and the alluvial mind: Presidential address 1595
Richard N. Bolton, MD
Portland, Oregon

Therapeutic donor insemination: A prospective randomized trial of fresh versus frozen sperm 1597
Leslee L. Subak, MD, G. David Adamson, MD, and Nancy L. Boltz, RNC
Stanford and Palo Alto, California

A prospective randomized trial of 57 women undergoing therapeutic donor insemination resulted in a 20.6% cycle fecundity with fresh sperm versus 9.4% with frozen ($p < 0.03$).

Effect of controlled ovarian hyperstimulation on pregnancy rates after intrauterine insemination 1607
Sheila J. DiMarzo, PhD, Joseph F. Kennedy, MD, Philip E. Young, MD, Stephen A. Hebert, MD, Dianne C. Rosenberg, MD, and Benito Villanueva, MD
San Diego, California

Intrauterine insemination after human menopausal gonadotropin stimulation yields a significantly higher pregnancy rate and monthly fecundability as compared with intrauterine insemination without ovulation induction or clomiphene treatment.

CEFOTAN® IM/IV
(cefotetan disodium)
Available in 1-gram and 2-gram vials

For Intravenous or Intramuscular Use
PLEASE SEE FULL PRESCRIBING INFORMATION FOR A COMPLETE DESCRIPTION.
A BRIEF SUMMARY FOLLOWS.

INDICATIONS AND USAGE
TREATMENT

CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary Tract Infections caused by *E. coli, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis,* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).

Lower Respiratory Tract Infections caused by *Streptococcus pneumoniae* (formerly *D. pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K. pneumoniae*), *E. coli, Proteus mirabilis,* and *Serratia marcescens**.

Skin and Skin Structure Infections due to *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes, Streptococcus* species (excluding enterococci), *Escherichia coli, Klebsiella pneumoniae, Peptococcus niger*, Peptostreptococcus* species.

Gynecologic Infections caused by *Staphylococcus aureus* (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *Streptococcus agalactiae, E. coli, Proteus mirabilis, Neisseria gonorrhoeae,* Bacteroides species (excluding *B. distasonis, B. ovatus, B. thetaiotaomicron*), *Fusobacterium* species*, and gram-positive anaerobic cocci (including *Peptococcus niger* and *Peptostreptococcus* species).

Cefotetan, like other cephalosporins, has no activity against *Chlamydia trachomatis.* Therefore, when cephalosporins are used in the treatment of pelvic inflammatory disease, and *C. trachomatis* is one of the suspected pathogens, appropriate antichlamydial coverage should be added.

Intra-abdominal Infections caused by *E. coli, Klebsiella* species (including *K. pneumoniae*), *Streptococcus* species (excluding enterococci), *Bacteroides* species (excluding *B. distasonis, B. ovatus, B. thetaiotaomicron*) and *Clostridium* species*.

Bone and Joint Infections caused by *Staphylococcus aureus**.

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic *in vitro* against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

PROPHYLAXIS

The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (e.g., cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

BEFORE THERAPY WITH CEFOTAN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOTETAN DISODIUM, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. IF THIS PRODUCT IS TO BE GIVEN TO PENICILLIN-SENSITIVE PATIENTS, CAUTION SHOULD BE EXERCISED BECAUSE CROSS-HYPERSENSITIVITY AMONG BETA-LACTAM ANTIBIOTICS HAS BEEN CLEARLY DOCUMENTED AND MAY OCCUR IN UP TO 10% OF PATIENTS WITH A HISTORY OF PENICILLIN ALLERGY. IF AN ALLERGIC REACTION TO CEFOTAN OCCURS, DISCONTINUE THE DRUG. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE TREATMENT WITH EPINEPHRINE AND OTHER EMERGENCY MEASURES, INCLUDING OXYGEN, INTRAVENOUS FLUIDS, INTRAVENOUS ANTIHISTAMINES, CORTICOSTEROIDS, PRESSOR AMINES AND AIRWAY MANAGEMENT, AS CLINICALLY INDICATED.

Pseudomembranous colitis has been reported with nearly all antibacterial agents, including cefotetan, and may range from mild to life-threatening. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment or surgical prophylaxis. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is a primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to discontinuation of the drug alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *Clostridium difficile.*

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated.

PRECAUTIONS

General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

Drug/Laboratory Test Interactions: The administration of CEFOTAN may result in a false-positive reaction for glucose in the urine using Clinitest®†, Benedict's solution, or Fehling's solution. It is recommended that glucose tests based on enzymatic glucose oxidase be used.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

Pregnancy: Teratogenic Effects. Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies, the following adverse effects were considered related to CEFOTAN therapy. Those appearing in italics have been reported during postmarketing experience.

Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700); *pseudomembranous colitis.* Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment or surgical prophylaxis. (See WARNINGS.)

Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300); *agranulocytosis, hemolytic anemia, leukopenia, thrombocytopenia,* and *prolonged prothrombin time.*

Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700); *anaphylactic reactions.*

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

Miscellaneous: *Fever*

In addition to the adverse reactions listed above which have been observed in patients treated with cefotetan, the following adverse reactions and altered laboratory tests have been reported for cephalosporin-class antibiotics: urticaria, pruritis, Stevens-Johnson syndrome, erythema multiforme, toxic epidermal necrolysis, vomiting, abdominal pain, colitis, superinfection, vaginitis including vaginal candidiasis, renal dysfunction, toxic nephropathy, hepatic dysfunction including cholestasis, aplastic anemia, hemorrhage, increased BUN, increased creatinine, elevated bilirubin, pancytopenia, and neutropenia.

Several cephalosporins have been implicated in triggering seizures, particularly in patients with renal impairment when the dosage was not reduced (see DOSAGE AND ADMINISTRATION and OVERDOSAGE). If seizures associated with drug therapy occur, the drug should be discontinued. Anticonvulsant therapy can be given if clinically indicated.

DOSAGE AND ADMINISTRATION
TREATMENT

The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Skin & Skin Structure		
Mild-Moderate[a]	2 grams	2 g every 24 hours IV 1 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6 grams[b]	3 g every 12 hours IV

[a] *K. pneumoniae* skin and skin structure infections should be treated with 1 or 2 grams every 12 hours IV or IM.

[b] Maximum daily dosage should not exceed 6 grams.

If *C. trachomatis* is a suspected pathogen in gynecologic infections, appropriate antichlamydial coverage should be added, since cefotetan has no activity against this organism.

PROPHYLAXIS

To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION

When renal function is impaired, a reduced dosage schedule must be employed. See FULL PRESCRIBING INFORMATION for a complete description.

NOTE: Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Deoxyribonucleic acid analysis by flow cytometry of uterine leiomyosarcomas and smooth muscle tumors of uncertain malignant potential 1646
William A. Peters III, MD, Donald R. Howard, MD, PhD, Willie A. Andersen, MD, and David C. Figge, MD
Seattle, Washington, and Charlottesville, Virginia

Proliferative rate rather than ploidy status is best correlated with survival in patients with leiomyosarcoma or smooth muscle tumors of uncertain malignant potential.

The utility of immunocytochemistry in invasive adenocarcinoma of the cervix 1655
Hisham K. Tamimi, MD, Allen M. Gown, MD, Jessie Kim-Deobald, MD, David C. Figge, MD, Benjamin E. Greer, MD, and Joanna M. Cain, MD
Seattle, Washington

Vimentin expression was consistently negative in patients with invasive adenocarcinoma of the cervix, and immunocytochemistry might be of benefit in evaluating such patients.

Advanced epithelial ovarian carcinoma: Long-term survival experience at the community hospital 1663
Ronald F. Unzelman, MD
Santa Rosa, California

Survival of community hospital–treated advanced ovarian cancer patients can be improved; early diagnosis, platinum-based chemotherapy, and cytoreduction to minimal disease are the contributing factors.

Brachial plexus palsy: An old problem revisited 1673
Raymond J. Jennett, MD, Theodore J. Tarby, MD, and Carol J. Kreinick, MA
Phoenix, Arizona

Brachial plexus palsy, which is commonly attributed to birth trauma, may occur as an intrauterine event.

Modified retropubic cystourethropexy II 1678
John A. Goodno, Jr., MD, and Thomas W. Powers, MD
Arcadia, California

Modified retropubic cystourethropexy was performed on 135 patients with urinary stress incontinence; a clinical success rate of 91.5% was achieved.

The physiologic mechanisms of variable decelerations 1683
Robert H. Ball, MD, and Julian T. Parer, MD, PhD
San Francisco, California

The asphyxial effect of variable decelerations may depend on whether the cause is umbilical cord compression or an independent vagal reflex.

Contents continued from page 9A

Elective induction versus spontaneous labor: A retrospective study of complications and outcome 1690
James A. Macer, MD, Cynthia L. Macer, MD, and Linda S. Chan, PhD
Pasadena, California

When compared with spontaneous labor, elective induction of labor at term does not appear to pose an increased risk to the mother or her fetus in a carefully selected patient population.

Tubal sterilization and risk of subsequent hospital admission for menstrual disorders 1698
Kirk K. Shy, MD, Andy Stergachis, PhD, Louis G. Grothaus, MS, Edward H. Wagner, MD, Julia Hecht, PhD, and Garnet Anderson, PhD
Seattle, Washington

Sterilized women had more hospitalizations for menstrual disorders than nonsterilized women.

Early amniocentesis: Outcome, risks, and technical problems at ≤12.8 weeks 1707
Frederick W. Hanson, MD, Frances Tennant, PhD, Stacy Hune, MS, and Karen Brookhyser, MS
Davis, California

Ultrasonographically guided amniocentesis at 12 weeks is a viable option for patients desiring earlier prenatal diagnosis.

TRANSACTIONS OF THE FIFTY-NINTH ANNUAL MEETING OF THE CENTRAL ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Suffer the little children: Presidential address 1712
James P. Youngblood, MD
Kansas City, Missouri

Anatomic aspects of vaginal eversion after hysterectomy 1717
John O. L. DeLancey, MD
Ann Arbor, Michigan

The fibers of the upper paracolpium suspend the vaginal apex from the pelvic walls and prevent eversion of the vagina.

Receiver-operator characteristic, efficiency analysis, and predictive value of serum progesterone concentration as a test for abnormal gestations 1729
Bryan D. Cowan, MD, David T. Vandermolen, MD, Cecil A. Long, MD, and Neil S. Whitworth, PhD
Jackson, Mississippi

Serum progesterone concentration <10 ng/ml predicts that 90% of pregnancies are abortive or ectopic.

Contents

Prevalence of out-of-phase endometrial biopsy specimens 1738
Albert J. Peters, DO, Riley P. Lloyd, MD, and Carolyn B. Coulam, MD
Indianapolis, Indiana

The prevalence of out-of-phase endometrial biopsy specimens among infertile patients, patients with recurrent pregnancy loss, or fertile controls does not differ when ultrasonographic documentation of ovulation is used as a reference point.

Drug use or inadequate prenatal care? Adverse pregnancy outcome in an urban setting 1747
Fredrik F. Broekhuizen, MD, John Utrie, DO, Chris Van Mullem, RN
Milwaukee, Wisconsin

Adequacy of prenatal care in patients with drug use in pregnancy affects perinatal outcome more than does drug use itself and marks life-style chaos.

Eclampsia: VII. Pregnancy outcome after eclampsia and long-term prognosis 1757
Baha M. Sibai, MD, Cem Sarinoglu, MD, and Brian M. Mercer, MD
Memphis, Tennessee

Women with eclampsia are at increased risk for subsequent preeclampsia (24%), eclampsia (1.9%), and chronic hypertension, particularly in women with eclampsia developing before 30 weeks.

Preoperative and postoperative analysis of site-specific pelvic support defects in 81 women treated with sacrospinous ligament suspension and pelvic reconstruction 1764
Bobby L. Shull, MD, Charles V. Capen, MD, Mark W. Riggs, PhD, and Thomas J. Kuehl, PhD
Temple, Texas

Preoperative and postoperative site-specific analysis of pelvic support defects enables a description of factors that affect long-term outcome of pelvic reconstructive surgery.

Cervical cytology: A randomized comparison of four sampling methods 1772
Marian L. McCord, MD, Thomas G. Stovall, MD, Janel L. Meric, MD, Robert L. Summitt, Jr., MD, and Sidney A. Coleman, MD
Memphis, Tennessee

The efficacy of four commercially available cervical cell sampling devices was compared.

Interlaboratory variation in antiphospholipid antibody testing 1780
Alan M. Peaceman, MD, Richard K. Silver, MD, Scott N. MacGregor, DO, and Michael L. Socol, MD
Chicago and Evanston, Illinois

Comparison of antiphospholipid antibody testing in 10 laboratories revealed significant variation in both methods and results.

Reproductive outcome in women with recurrent spontaneous abortions of alloimmune and autoimmune causes: Preconception versus postconception treatment 1787
Joanne Y.H. Kwak, MD, Alice Gilman-Sachs, PhD, Kenneth D. Beaman, PhD, and Alan E. Beer, MD
North Chicago, Illinois

Preconception treatment for autoimmune abnormalities in women with recurrent spontaneous abortions resulted in better reproductive outcome than no treatment or postconception treatment.

The Green Bay cesarean section study: II. The physician factor as a determinant of cesarean birth rates for failed labor 1799
Robert K. DeMott, MD, and Herbert F. Sandmire, MD
Green Bay, Wisconsin

In nonprogressive labor the management techniques differed significantly for physicians with low (4.3%) versus high (12.3%) rates of cesarean section with no differences in neonatal or maternal outcomes.

Vaginal birth after cesarean delivery: Are there useful and valid predictors of success or failure? 1811
Mark G. Pickhardt, MD, James N. Martin, Jr., MD, Edward F. Meydrech, PhD, Pamela G. Blake, RN, MSN, Rick W. Martin, MD, Kenneth G. Perry, Jr., MD, and John C. Morrison, MD
Jackson, Mississippi

Statistical attempts to use prenatal and obstetric data to predict the outcome of individual attempts of vaginal birth after cesarean section in our patient population lacked sensitivity and specificity.

Comparison of dynamic image and pulsed Doppler ultrasonography for the diagnosis of the small-for-gestational-age fetus 1820
Joseph M. Miller, Jr., MD, and Harvey A. Gabert, MD
New Orleans, Louisiana

Small-for-gestational-age fetuses were better identified by standard ultrasonography than by Doppler velocimetry of the umbilical artery.

Prediction of respiratory distress syndrome by a new colorimetric assay 1827
Rami Almog, PhD, John W. Goldkrand, MD, Regina A. Saulsbery, BS, and Carol Samsonoff, MS
Albany, New York, and Savannah, Georgia

A novel colorimetric assay for fetal lung maturity assessment was developed; it was shown to be reliable in predicting respiratory distress syndrome.

Urinary incontinence: Correlation of history and brief office evaluation with multichannel urodynamic testing 1835
Robert L. Summitt, Jr., MD, Thomas G. Stovall, MD, Alfred E. Bent, MD, and Donald R. Ostergard, MD
Memphis, Tennessee, and Long Beach, California

A patient's history and a brief office evaluation did not reliably predict the etiologic factors of urinary incontinence.

Contents

Mechanism of recurrent spontaneous abortion: I. Ultrasonographic findings 1844
J. Jaroslav Stern, MD, and Carolyn B. Coulam, MD
Indianapolis, Indiana

A single transvaginal sonogram can predict 92% of pregnancy losses at 6 weeks of gestation.

Acute childbirth morbidity: Its measurement using hospital charges 1853
Marvin L. Hage, MD, Michael J. Helms, BS, Adams Dudley, MBA, William W. Stead, MD, William E. Hammond, PhD, Catherine Neyland, MHA, and Charles B. Hammond, MD
Durham, North Carolina

Analysis of severity of acute childbirth morbidity showed marked variation of diagnosis and risk-specific charges for patients delivered by primary cesarean section.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318 USA; phone (314) 453-4394. In the U.S., call toll-free: 1-800-325-4177, ext. 4394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Authorization to photocopy items for internal or personal use is granted by Mosby–Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. The U.S. Government retains a nonexclusive, royalty-free license in and to any copyright on articles authored by government employees. 0002-9378/92 $00.00 + .10.

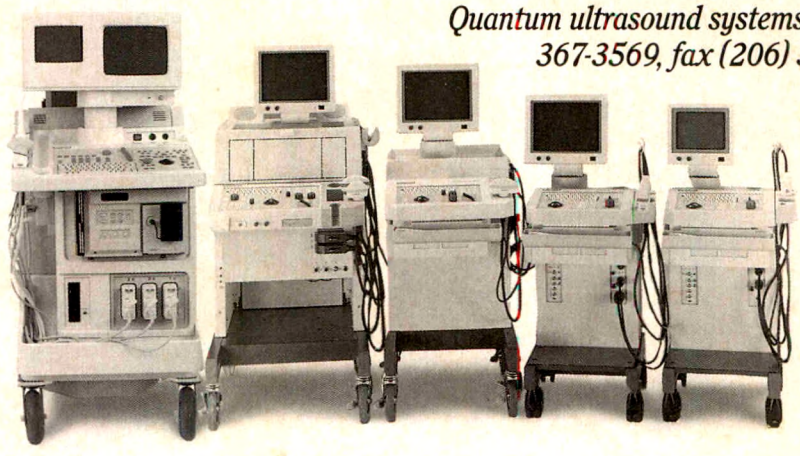
You Have All Kinds Of Reasons To Stay At The Forefront Of Ultrasound.

We Have The Technology To Keep You There.



In offices, clinics and hospitals worldwide, Siemens Quantum is changing the way doctors look at their patients.

Our imaging systems and state-of-the-art diagnostics are pushing the limits of ultrasound. Providing more and better information at every level. Performing more types of obstetric and gynecologic studies than ever before.

The Siemens Quantum alliance joins two powerful forces: Siemens, the world's largest medical imaging company, and Quantum, a pioneer and technological leader in ultrasound.

Together, we're committed to maintaining our leading edge. Which means keeping our systems—and our customers—at the forefront of diagnostic imaging.

The Siemens SONOLINE® SI-200 & 250 are versatile, affordable, compact and easy to use.

And they come with the most advanced, multi-frequency, patient-friendly endovaginal probe on the market.

The Siemens SONOLINE® SI-450 offers superb image quality and a comprehensive set of reports and measurement packages. For complete transabdominal, endovaginal and spectral Doppler capabilities, there's no better equipment for the price.

The Quantum 2000 is a high-performance, high-end, all-purpose system that's unsurpassed for high-definition gray scale and ultra-sensitive color flow. Its advanced technology lets you see subtle differences in tissue, accurately image the tiniest flows, and detect even the smallest details at depth.

To receive more information on Siemens Quantum ultrasound systems, call 1-800-367-3569, fax (206) 391-9161, or write us at 1040 12th Ave. N.W., Issaquah, WA 98027.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors (N Engl J Med 1991;324:424-8). Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern and southeastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. J. Peter Van Dorsten, P.O. Box 34, MCV Station, Richmond, VA 23298.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's suggested reviewers. When authors submit their manuscripts, they must provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. If not completed in full, it will be returned to the author for completion. The copyright statement and checklist form may be torn from the JOURNAL or photocopied for submission.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) or some of the same authors has been previously published in any medium that deals in any respect whatsoever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article(s) or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. Two copies of a new manuscript being prepared for possible publication also must be submitted. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and nonhuman experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the

requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the *Material and Methods* section of the submitted manuscript. Reports of experiments on nonhuman animals or other species must *state in the* Material and Methods *section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The type of nonhuman animals or other species used in an investigation must be named in the title, abstract, key words, and *Material and Methods* section of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. *In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.*

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of black-and-white glossy prints of illustrations are required. See "Color figures" and "Computer-generated figures" for special requirements. Manuscripts must be submitted in English.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. *At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).*

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page including key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Below the abstract, list 3 to 5 *key words or short phrases* for indexing purposes.

A structured abstract is required for certain types of articles and a *standard abstract format* is required for other types of articles; therefore the author(s) should select and prepare the appropriate abstract to be used in the submitted manuscript. This applies to both independently submitted and society manuscripts.

Structured abstract. A structured abstract, limited to 150 words, is to be used for regular articles, society articles, and Current Investigation articles; excluded are Clinical Opinion, Current Development, case report, and brief communication articles. The structured abstract is to contain the following major headings: *Objective(s); Study Design; Results;* and *Conclusion(s).* The *Objective(s)* reflects the purpose of the study, that is, the hypothesis that is being tested. The *Study Design* should include the setting for the study, the subjects (number and type), the treatment or intervention, and the type of statistical analysis. The *Results* include the outcome of the study and statistical significance if appropriate. The *Conclusion(s)* states the significance of the results.

Standard abstract. The standard abstract format is required for Clinical Opinion, Current Development, case report, and brief communication articles. The standard abstracts for Clinical Opinion and Current Development articles are to be 50 to 150 words and standard abstracts for case reports and brief communications are limited to 50 words. Even though the formal names of these four types of articles are not used, an author should determine his/her type of manuscript and prepare the appropriate standard abstract, regardless of whether it is to be submitted independently or as a part of a society's transactions.

Text. Do not hesitate to write your manuscript in the first person and active voice if they are more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through *Comment* section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

Council of Biology Editors Style Manual or the AMA's *Manual of Style.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify *Material and Methods*, *Results*, and *Comment*. Authors may wish to summarize their findings in a short paragraph at the end of the *Comment* section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to repeat the study) the plan, the patients, experimental animals or other species, material, and controls, the methods and procedures utilized, and the statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the *Comment* section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the *Results* section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (N Engl J Med 1991;324:424-8). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. *This signed permission must accompany the manuscript when it is submitted to the Editor.* Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page if the color balance is appropriate.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

LIBRARY

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed together in numeric order double-spaced on one sheet of paper (or more if necessary) separate from the text of the manuscript. This page must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from *the copyright owner and original author* along with complete reference information. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for certain types of manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include *standard abstract format*, of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article. The abstract *must* follow the *structured format*.

Clinical Opinion. Limit of 3000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. *Letters to the Editors* must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name[s] and address[es] of the signer[s], and the phrase "To the Editors"). The submitted *Letter to the Editors* must be accompanied by a signed copyright statement. If there are two or more signers of the *Letter to the Editors,* one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all cosigners." These requirements apply to all types of *Letters to the Editors*. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A *Letter to the Editors* commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a *Letter to the Editors* will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (1-800-325-4177, ext. 4306, or 314-453-4306).

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The completed checklist is enclosed. The assignment of copyright signed by **all** authors accompanies the manuscript.
—Human experimentation has been approved by the local institution as stated in the *Material and Methods* section.
—Guidelines for the care and use of *nonhuman* animals or *other species* approved by the institution have been followed as indicated in the *Material and Methods* section. *The species is named in the title, abstract, key words, and* Material and Methods *section.*
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed in English double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, structured or standard abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any coauthors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author and/or some of the coauthors have previously published, have submitted for possible publication, or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities, differences and explanation are provided in the covering letter that accompanies the submitted manuscript.

Reviewers

—Names and addresses of three suggested reviewers are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title.
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than United States in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the institutional affiliation(s) of the author(s) at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract and key words or short phrases

—The abstract (structured or standard format) is typed double-spaced with required margins on page 3 headed by the title and author(s) name(s). Beneath the abstract 3 to 5 key words or short phrases are typed.
—A *structured abstract,* with 150 words or less, is submitted as required for regular articles, society regular-type articles, and Current Investigation articles. The abstract contains the four required major headings: Objective(s), Study Design, Results, and Conclusion(s), each with a brief adequate presentation.
—A *standard abstract* is submitted as required for Clinical Opinion and Current Development articles with 50 to 150 words and for case reports and brief communications articles with a maximum of 50 words, be they independent or society articles.

References

—Are typed double-spaced.
—Are numbered consecutively in the order they are cited in the text.
—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors have been followed.
—Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Figures

—Each is numbered with an Arabic numeral and cited in numeric sequence in the text.
—Three sets of unmounted glossy prints for *black-and-white* figures are submitted, properly numbered, labeled, and *top indicated* on the back of each print.
—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back and *top indicated* are submitted. None are dot matrix or photographic prints.
—Original transparencies of *color photographs* appropriately numbered and identified and *top indicated* are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

Figure legends

—Are provided for each figure.
—Are numbered and typed together in numeric order on one sheet of paper (more if necessary). The page is numbered in sequence after the References page(s).

Tables

—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in numeric sequence in the text.

NORPLANT® SYSTEM
levonorgestrel implants

Lasts 5 years...yet is reversible

Serious as well as minor side effects may occur. The most common side effect which has been observed is menstrual bleeding irregularities.

Please see brief summary of prescribing information on the following page.

©1992, Wyeth-Ayerst Laboratories. 70443B

NORPLANT® SYSTEM

levonorgestrel implants

Lasts five years…yet is reversible

BRIEF SUMMARY OF PRESCRIBING INFORMATION. CONSULT THE PACKAGE LITERATURE FOR FULL PRESCRIBING INFORMATION.

Indications and Usage

The NORPLANT SYSTEM is indicated for the prevention of pregnancy and is a long-term (up to 5 years) reversible contraceptive system. The capsules should be removed by the end of the 5th year. New capsules may be inserted at that time if continuing contraceptive protection is desired.

Contraindications

1. Active thrombophlebitis or thromboembolic disorders. 2. Undiagnosed abnormal genital bleeding. 3. Known or suspected pregnancy. 4. Acute liver disease; benign or malignant liver tumors. 5. Known or suspected carcinoma of the breast.

Warnings

A. WARNINGS BASED ON EXPERIENCE WITH THE NORPLANT SYSTEM

1. *Bleeding Irregularities* — Most women can expect some variation in menstrual bleeding patterns. Irregular menstrual bleeding, intermenstrual spotting, prolonged episodes of bleeding and spotting, and amenorrhea may occur, and could mask symptoms of cervical or endometrial cancer. Overall, these irregularities diminish with continued use. Because amenorrhea may occur, missed menstrual periods cannot serve as the only identifier of early pregnancy. Perform pregnancy tests whenever pregnancy is suspected. If pregnancy occurs, the capsules must be removed. Hemoglobin concentrations found in clinical trials generally indicated that reduced menstrual blood loss is associated with NORPLANT SYSTEM use. Blood loss resulting in hemoglobin values consistent with anemia occurred rarely.

2. *Delayed Follicular Atresia* — Atresia of the follicle is sometimes delayed, resulting in enlarged follicles that are clinically indistinguishable from ovarian cysts. In the majority of women, enlarged follicles disappear spontaneously. Rarely, they twist or rupture and surgical intervention may be required.

3. *Ectopic Pregnancies* — Ectopic pregnancies have occurred among NORPLANT SYSTEM users, although clinical studies have shown no increase in the rate of ectopic pregnancies per year among NORPLANT SYSTEM users as compared with users of no method or of IUDs. The incidence among NORPLANT SYSTEM users (1.3 per 1000 woman-years) was significantly below the rate estimated for noncontraceptive users in the U.S. (2.7 to 3.0 per 1000 woman-years). Ectopic pregnancy risk may increase with duration of NORPLANT SYSTEM use and increased weight of the user. Rule out ectopic pregnancy in any patient presenting with lower-abdominal pain.

4. *Breast-feeding* — Steroids are not the contraceptives of first choice for lactating women. Levonorgestrel has been identified in breast milk. Limited data suggests no significant effects on infant growth or health when mothers used the NORPLANT SYSTEM beginning 6 weeks after parturition.

5. *Foreign-body Carcinogenesis* — Rarely, cancers occur at foreign-body intrusion sites or old scars. None has been reported in NORPLANT SYSTEM clinical trials and risk to users is judged to be minimal.

6. *Thromboembolic Disorders* — Remove capsules if active thrombophlebitis or thromboembolic disease develops. With prolonged immobilization removal should be considered.

B. WARNINGS BASED ON EXPERIENCE WITH COMBINATION (PROGESTIN PLUS ESTROGEN) ORAL CONTRACEPTIVES (OCs)

Note: Many of the side effects or risks listed below are thought to be estrogen-related: the association of the NORPLANT SYSTEM progestin-only method to these risks is unknown.

1. *Cigarette Smoking* — Cigarette smoking increases the risk of serious cardiovascular side effects from combined OC use. Risk increases with age and heavy smoking (≥15 cigarettes/day) and is quite marked in women over 35 years old.

2. *Elevated Blood Pressure* — Increase in blood pressure has been reported in combination OC users; prevalence increases with long exposure.

3. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease is associated with combination OC use. Estimate of relative risk is 4- to 11-fold higher for users vs. nonusers.

Cerebrovascular Disorders: Combination OCs increase the relative and attributable risk of cerebrovascular events (thrombotic and hemorrhagic strokes). Generally, risk is greatest among hypertensive women > 35 years of age who smoke.

Myocardial Infarction (MI): An increased risk of MI has been attributed to combined OC use. This is thought to be primarily thrombotic in origin and related to the estrogen component. Increased risk occurs primarily in smokers or women with other underlying risk factors for coronary-artery disease. Relative risk of heart attack for combined OC users is estimated as 2 to 6 times that for nonusers. Absolute risk is very low for women under 30 years old.

Studies indicate a significant trend toward higher MI and stroke rates with increased progestin doses in combination OCs. However, recent data indicated no increased MI risk with past use of levonorgestrel-containing OCs.

4. *Carcinoma* — Recent evidence in the literature suggests no association between OC use and increased risk of breast cancer in the overall population of users. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. Some of these same studies have shown an increased relative risk of breast cancer in certain subgroups; no consistent pattern has been identified. Some studies suggest an association between combination OCs and an increase in the risk of cervical intra-epithelial neoplasia in some populations of women. The extent to which such findings may be due to differences in sexual behavior and other factors remains controversial. A cause-and-effect relationship between combined OC use and breast or cervical cancer has not been established. Combination OCs may decrease ovarian and endometrial cancer risk. Irregular bleeding patterns associated with NORPLANT SYSTEM use could mask cervical or endometrial cancer symptoms.

5. *Hepatic Tumors* — Hepatic adenomas are associated with combination OC use; estimated incidence is 3 events per 100,000 users per year. Risk increases after 4 or more years of use. Hepatic adenomas are benign but may rupture and cause death through intra-abdominal hemorrhage.

6. *Ocular Lesions* — Retinal thrombosis is associated with OC use and is believed to be related to the estrogen component. However, NORPLANT SYSTEM capsules should be removed if there is unexplained partial or complete vision loss; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Undertake appropriate diagnostic and therapeutic measures immediately.

7. *Use Before or During Early Pregnancy* — Extensive epidemiological studies reveal no increased risk of birth defects when OCs are used prior to pregnancy. Studies also do not suggest a teratogenic effect when taken inadvertently during early pregnancy. No evidence suggests that risk with NORPLANT SYSTEM use is different.

8. *Gallbladder Disease* — Early studies reported an increased lifetime relative risk of gallbladder surgery in OC or estrogen users. More recent studies, however, indicate that the relative risk of gallbladder disease with OC use may be minimal; this may be related to use of OCs with less estrogen and progestin content.

Precautions

GENERAL:

1. *Physical Examination and Follow-up* — A complete medical history and physical examination should be taken prior to implantation or reimplantation of NORPLANT SYSTEM capsules and at least annually during its use. Exams should include special reference to the implant site, blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. Rule out malignancy in cases of undiagnosed, persistent or recurrent abnormal vaginal bleeding. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. *Carbohydrate Metabolism* — Altered glucose tolerance is found in some combination and progestin-only OC users. Effects of NORPLANT SYSTEM on carbohydrate metabolism appear minimal. Observe diabetic and prediabetic patients carefully while using the NORPLANT SYSTEM. Follow women being treated for hyperlipidemias closely if using the NORPLANT SYSTEM. Some progestins may elevate LDL and may render control of hyperlipidemias more difficult. (See **Warnings**.)

3. *Liver Function* — Consider removing capsules if jaundice develops. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. *Fluid Retention* — Steroid contraceptives may cause some degree of fluid retention. Prescribe with caution, and careful monitoring, in patients with conditions possibly aggravated by fluid retention.

5. *Emotional Disorders* — Consider removing capsules if significant depression occurs since the symptom may be drug-related. Observe carefully those with history of depression and consider removal if depression recurs to a serious degree.

6. *Contact Lenses* — Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. *Insertion and Removal* — Insertion is advised during the first 7 days of the cycle or immediately following abortion to insure that the woman is not pregnant and to assure contraceptive effectiveness during first cycle of use. Capsules may be inserted at any time during the cycle provided pregnancy has been excluded and a nonhormonal contraceptive method is used for the remainder of the cycle. Insertion is not recommended before 6 weeks postpartum in breast-feeding women. Follow insertion and removal instructions closely. Healthcare professionals are strongly advised to be instructed in the procedures before they attempt them. Proper insertion just under the skin facilitates removals; proper insertion and removal should result in minimal scarring. If all capsules cannot be removed at first attempt, attempt removal later when the site has healed. Bruising may occur at implant site during insertion or removal. Hyperpigmentation may occur at implant site but is usually reversible following removal. **See Full Prescribing Information for Detailed Insertion/Removal Instructions.**

8. *Infections* — Implant site infection has been uncommon (0.7%); aseptic technique and proper insertion/removal reduces possibility of infection. Institute treatment if infection occurs; remove capsules if infection persists.

9. *Expulsion* — Expulsion of capsules was uncommon; frequency increased when capsule placement was extremely shallow, was too close to incision, or when infection was present. Replace expelled capsule with new sterile capsule. Treat and cure any infection before replacement. Contraceptive efficacy may be inadequate with fewer than 6 capsules.

10. *Provisions for Removal* — Advise women that capsules may be removed at any time for any reason. Personnel instructed in removal technique should perform removal on request or at the end of 5 years of usage. Upon removal, dispose of capsules in accordance with Centers for Disease Control Guidelines for biohazardous waste.

DRUG INTERACTIONS: Reduced efficacy (pregnancy) in NORPLANT SYSTEM users has been reported when phenytoin or carbamazepine were used concomitantly. Warn NORPLANT SYSTEM users of possible decreased efficacy with use of related drugs.

DRUG/LABORATORY TEST INTERACTIONS: 1. Sex-hormone-binding globulin concentrations are decreased. 2. Thyroxine concentrations may be slightly decreased and triiodothyronine uptake increased.

CARCINOGENESIS: See **Warnings** section and Full Prescribing Information.

PREGNANCY: Pregnancy Category X. See **Warnings** section and Full Prescribing Information.

NURSING MOTHERS: See **Warnings** section and Full Prescribing Information.

INFORMATION FOR THE PATIENT: See Patient Labeling. Provide copy of patient labeling to the patient. Advise patients that Prescribing Information is available upon request. Inform prospective users of risks and benefits associated with NORPLANT SYSTEM use, with other forms of contraception, with no contraception, and about insertion/removal procedures. Informed consent from all patients may be desired in light of techniques involved with insertion and removal.

Adverse Reactions

The following have been associated with the NORPLANT SYSTEM during first year of use: many bleeding days or prolonged bleeding (27.6%); spotting (17.1%); amenorrhea (9.4%); irregular (onsets of) bleeding (7.6%); frequent bleeding onsets (7.0%); scanty bleeding (5.2%); pain or itching near implant site - usually transient - (3.7%); infection at implant site (0.7%); removal difficulties affecting subjects - based on 849 removals - (6.2%).

Controlled clinical studies suggest that the following, occurring during the first year, are probably associated with NORPLANT SYSTEM use: headache; nervousness; nausea; dizziness; adnexal enlargement; dermatitis; acne; change of appetite; mastalgia; weight gain; hirsutism, hypertrichosis and scalp-hair loss. The following were reported with a frequency of 5% or greater during the first year and possibly may be related to NORPLANT SYSTEM use: breast discharge; cervicitis; musculoskeletal pain; abdominal discomfort; leukorrhea; vaginitis.

Overdosage

Overdosage may cause fluid retention with its associated effects and uterine bleeding irregularities.

Dosage and Administration

The NORPLANT SYSTEM consists of six Silastic® capsules, each containing 36 mg of the progestin levonorgestrel. The total administered (implanted) dose is 216 mg. Implantation of all six capsules should be performed during the first 7 days of the onset of menses by a healthcare professional instructed in the NORPLANT SYSTEM insertion technique. Insertion is subdermal in the midportion of the upper arm about 8 to 10 cm above the elbow crease. Distribution should be in a fanlike pattern, about 15 degrees apart, for a total of 75 degrees. Proper insertion will facilitate later removal. **(See Full Prescribing Information for Detailed Insertion/Removal Instructions.)**

Folly, woodenheadedness, and the alluvial mind

Presidential address

Richard N. Bolton, MD

Portland, Oregon

One of my favorite authors wrote about history. If you think history is dull, I invite you to read any of Barbara W. Tuchman's books. They are as historic nonfiction should be—well documented, concise, exciting, and filled with the kind of insight that makes the past actions of mankind very much alive.

In my view, her finest book is *The March of Folly.*[1] Folly, she contends, "is the pursuit by governments of policy contrary to their own self-interest." Self-interest is composed of those ideas and policies that benefit the body being governed; folly is "policy which is counter productive." To qualify as folly, a policy must meet three criteria: First, "it must have been perceived as counter-productive in its own time"; second, "a feasible alternative course of action must have been available," and third, "the policy in question should be that of the group, not an individual."[2]

In *The March of Folly,* Tuchman details some prime examples: the Trojan horse, how George III of England and his advisers lost America, the excesses of the Renaissance popes that added fuel to the fire of reformation, the American involvement in a foolish, pointless war in Vietman, Louis XIV's revocation of the Edict of Nantes and the resulting persecution of the Huguenots, and the failure of Rehoboam, King of Israel, to repeal the heavy taxes imposed by his father, King Solomon. This folly in 930 BC resulted in the loss of the 10 northern tribes, destroying a kingdom put together by King David that had extended from northern Syria to Egypt. The emnity thus produced has caused war after war for 2800 years. The United States has just spent lives and a billion dollars a day fighting a new chapter in this same war and it is not over yet.

Regrettably, folly fueled by woodenheadedness is still with us. "Wooden-headedness is accessing a situation in terms of pre-conceived fixed notions while ignoring or rejecting contrary signs. It is acting according to wish while not allowing oneself to be deflected by the facts."[3] In other words, do not confuse me with facts, for my mind is made up. Woodenheadedness is alive and in full flower in Oregon. The governor of Oregon supported a specific tax intended to finance the increased cost of Medicaid. This tax was to be levied only on health care providers, totally ignoring societal responsibility. This same foolish concept could be applied to rent, automobiles, food, fire, police, bureaucrats, and lawyers. Happily, it did not get out of committee.

Another concept that helps explain curious political action is the "alluvial mind" "In such a mind, an idea develops so slowly that it hardly seems to have been there at all until it seems to have been there always."[4] The alluvial mind concept is described by William Irvine in his delightful book, *Apes, Angels and Victorians.*[4] This book is about Darwin, Huxley, and evolution. He describes Charles Darwin's concept of evolution as being alluvial with the whole having being derived from "tiny sands of evidence gradually accumulated during his long voyage on the *Beagle.*" This thought process is not geologic but rather the slow development of a concept until it is so engrained that its validity cannot be questioned.

The Supreme Court Title X "gag rule" decision seems a case in point. Family planning clinics accepting federal funds cannot mention abortion as a medical option. Ignore that this tramples on freedom of speech as guaranteed by the First Amendment. Ignore that

From The Womens Clinic.

Presented at the Fifty-eighth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Ashland, Oregon, September 9-12, 1991.

Reprints not available.

6/6/37158

this prevents health care workers from doing the best possible job of providing medically complete information. Ignore that this ruling comes awfully close to destroying the concept of separation of church and state; when life begins is a theologic argument and very difficult to document scientifically. Ignore the administrations' possible political pressure on the court; this pressure may have influenced this decision. Rather, focus on the term "federal funds." I submit that federal funds is an alluvial mind concept. There are no federal funds. Our government does not generate wealth. If it did, federal interest obligations would not be about $560 million a day,[5] and our 1991 federal deficit would not be $309 billion—the largest ever. Our government runs on red ink, and federal funds are our taxes. It would be nice if the citizen's funds were spent in a socially responsible manner.

Trade union, business, and government involvement in job-linked health insurance was born by accident during World War II.[6] The War Labor Board, to avoid inflation, put a ceiling on wages. So trade unions proposed "hidden" pay increases in the form of health insurance. The board gave approval and the alluvial mind concept of health insurance as a right was born.

Our legislatures have a real love-hate relationship with health care. This dilemma arises from the lure of office, fueled by the all-important need for reelection. The guiding principle in pursuing reelection is to "please as many and offend as few as possible."[7] Health care legislation is a positive source of votes; realistic health care funding, however, means higher taxes and will lose votes, a concept abhorrent to all politicians. There is no other way to explain the Veterans Administration Medical Service, the repeal of Medicare's catastrophic insurance, the underfunding of Medicaid, the Health Care Financing Administration's mauling of Medicare reimbursement, the emotions that have blocked investigation of RU 486 for nonabortion use, and the general silliness that has made acquired immunodeficiency syndrome a political disease instead of an infectious disease.

For these and many other reasons, the citizens of the United States cannot afford more politically motivated government meddling in health care. There is too much room for folly, woodenheadedness, and the alluvial mind. Folly and health care can be avoided. I sincerely urge you all to consider the American Medical Association's proposal for affordable quality health care: Health Access America.[8] It can be made to work for all and does not destroy the best health care in the world. Its salient points are as follows: (1) Improvements to the American health care system should preserve the strengths of our current system; (2) affordable coverage for appropriate health care should be available to all Americans regardless of income; (3) particular efforts are needed to assure continued access by the elderly to affordable health care services; (4) health care services should be delivered with high quality and appropriate costs; (5) patients should be free to determine from whom and the manner in which health care benefits are delivered; (6) all physicians should be committed to the highest ethical standards in the delivery of care to patients.

In my conception a health care system funded by taxes and administered entirely by the federal government would have the compassion of the Internal Revenue Service, the efficiency of the post office, a budget to make the Pentagon blush, and the overall benevolence of the Bureau of Indian Affairs.

After all, what can you expect from a government that outlaws Lawn Darts but lets us keep handguns.

Therapeutic donor insemination: A prospective randomized trial of fresh versus frozen sperm

Leslee L. Subak, MD, G. David Adamson, MD, and Nancy L. Boltz, RNC
Stanford and Palo Alto, California

OBJECTIVE: We evaluated the efficacy of fresh versus frozen sperm in therapeutic donor insemination.
STUDY DESIGN: Fifty-seven women underwent 72 courses of treatment (a maximum of six therapeutic donor insemination cycles—three fresh and three frozen) totaling 198 cycles. Each woman served as her own control and was prospectively randomized to receive a single, timed insemination of either fresh or frozen sperm.
RESULTS: Fecundity was 20.6% for fresh sperm cycles and 9.4% for frozen ($p < 0.03$, by χ^2 analysis). Fresh cervical cap insemination fecundity was 20.3%; frozen was 7.8% ($p < 0.03$, by χ^2 analysis). Fresh intrauterine insemination fecundity was 21.2%; frozen was 15.8% ($p = 0.63$, by χ^2 analysis). Fresh 3-month life-table pregnancy rates were 48% ± 10%; frozen rates were 22% ± 8% ($p = 0.05$ by Breslow analysis). Survival analysis with fixed covariates showed a positive association with the use of fresh sperm ($p = 0.04$).
CONCLUSION: Cycle fecundity was significantly greater with fresh sperm in women undergoing cervical cap insemination or intrauterine insemination and in women undergoing only cervical cap insemination. These results have important implications for contemporary management of patients undergoing therapeutic donor insemination with frozen sperm. (Am J Obstet Gynecol 1992;166:1597-1606.)

Key words: Fresh sperm, frozen sperm, therapeutic donor insemination

The American Fertility Society amended its therapeutic donor insemination guidelines in February 1988, stating that " . . . the use of fresh semen for donor insemination is no longer warranted."[1, 2] This statement responded to concern about human immunodeficiency virus (HIV) transmission in therapeutic donor insemination. Under the new guidelines only sperm from donors who are seronegative for HIV 6 months after sperm donation and freezing would be used. This change of guidelines has been controversial since many physicians believe that the use of fresh sperm results in increased pregnancy rates and/or fecundity as compared with those for frozen (cryopreserved) sperm. In addition, the risk of HIV infection after one insemination with fresh sperm from a screened donor is exceedingly remote, being approximately 1 in 500 million.[3] However, published reports have documented HIV infection after therapeutic donor insemination with sperm from asymptomatic HIV-positive donors.[4, 5]

There are many viral, bacterial, and parasitic pathogens in semen, and transmission of infectious agents has been reported in fresh semen.[6] The effects of freezing on these pathogens are not well documented, but freezing does not completely inactivate HIV, herpes simplex virus, cytomegalovirus, *Neisseria gonorrhoeae, Chlamydia trachomatis,* or the mycoplasmas.[7] The advantages of frozen semen include a quarantine period in storage with donor retesting before insemination. For HIV, this permits testing for proviral deoxyribonucleic acid with a polymerase chain reaction technique and testing for serum antibodies, neither of which may be in high enough concentrations for detection at the time of donation. Freezing of semen may also reduce the concentration of some pathogens.[6] Frozen sperm allows insemination when timing is optimal, multiple inseminations in a single cycle, and the use of the same donor for subsequent pregnancies.[8] Disadvantages of frozen sperm include a possibly decreased pregnancy rate and/or cycle fecundity and possibly more inseminations per cycle as compared with fresh sperm.[9-14] The decreased fecundity of frozen sperm is due, in part, to structural and functional damage resulting from the freezing process.[8, 9, 15, 16]

Few randomized, controlled comparisons of fresh versus frozen sperm in therapeutic donor insemination have been done, and ongoing trials with large patient

populations and current cryopreservation techniques are needed.[8, 11, 12, 17] This study compares the efficacy of fresh and frozen sperm in therapeutic donor insemination in a prospective, randomized clinical trial with each woman serving as her own control.

Material and methods

Patient selection and treatment. Couples presenting for therapeutic donor insemination at a referral infertility practice between June 1988 and December 1990 were given the option of receiving only frozen sperm or participating in this study and receiving randomized fresh and frozen sperm. Couples were thoroughly counseled of their options and the risks of fresh therapeutic donor insemination. This study was approved by the Stanford Committee for the Protection of Human Subjects in Research. All couples had male factor as one cause of infertility and underwent infertility screening consisting of basal body temperature graphing, urinary luteinizing hormone (LH) assay, serum progesterone measurement, cervical mucus evaluation, semen analysis, and *C. trachomatis* and mycoplasma cultures. Endometrial biopsy, postcoital test, hamster egg penetration assay, hysterosalpingography, laparoscopy, and laparotomy were performed as clinically indicated. Women had at least one patent fallopian tube and were ovulating either spontaneously or with clomiphene citrate or human menopausal gonadotropins (or both). Ovulatory dysfunction was defined as menstrual cycles <21 or >35 days in length or an abnormal luteal phase (two endometrial biopsy specimens >2 days out of phase). Endometriosis and adhesions were treated with carbon dioxide laser vaporization at surgery.

Couples agreed to six cycles of therapeutic donor insemination—three cycles with fresh and three cycles with frozen sperm. A course of treatment was defined as a maximum of six cycles of therapeutic donor insemination and was terminated by conception or withdrawal from the study. Insemination type (fresh or frozen) was prospectively assigned by random number tables, such that no more than two consecutive inseminations with either fresh or frozen sperm were performed. The protocol was established so that all fresh and frozen inseminations for a given patient used sperm from the same donor. In only five courses of treatment was it necessary at any time to use frozen sperm from a different donor. Women were not aware of the type of sperm they were receiving. A single insemination per cycle with either fresh or frozen sperm was performed within 12 to 36 hours of the LH surge with either cervical cap insemination or intrauterine insemination. Whole ejaculate was used for cervical cap insemination with fresh sperm, and 1 ml of thawed whole ejaculate was used for cervical cap insemination with frozen sperm. For intrauterine insemination a maximum of 0.5 ml of washed sperm was slowly infused with a 1 ml syringe and a 3.5 Fr TomCat catheter (Sherwood Medical, St. Louis) or a Makler cannula (Sefi Medical Instruments, Haifa). Women remained supine for 20 minutes with the cannula in place. They were given oral doxycycline (100 mg) the evening before intrauterine insemination as prophylaxis against infection. Indications for intrauterine insemination included poor cervical mucus determined by abnormal postcoital test (actively motile sperm <1/high-power field) or abnormal cervical mucus penetration test (<25 mm in 90 minutes), female serum Immunobead antisperm antibodies, and high-dose clomiphene citrate ovulation stimulation (at least 100 mg/day). Timing of ovulation was monitored with basal body temperature charts and LH urinary monoclonal antibody home testing (OvuQUICK, Monoclonal Antibodies, Mountain View, Calif.). If menses did not occur, a quantitative β-human chorionic gonadotropin (β-hCG) assay was done and repeated in 2 days to confirm pregnancy. If women did not conceive during their first course of treatment (six insemination cycles), they were given the option, during a second course of treatment, to enter the study again with the same donor or a different one. When women conceived on a nonprotocol cycle, they were terminated from the study with the status "not pregnant." When women had an insemination on a nonprotocol cycle, they continued on the same study "course of treatment" with appropriate randomization in the next cycle. When a women conceived on a study protocol cycle, she was terminated from the study with the status "pregnant." After spontaneous abortion or delivery, women were reentered in a new "course of treatment" with randomized inseminations beginning with cycle 1. Data were recoded for the subsequent cycle to reflect changes in parameters such as age, gravidity, and duration of infertility.

Sperm preparation. Fresh ejaculates were allowed to liquefy for 30 minutes at 37° C, then suspended in a 1:1 ratio with TEST-yolk buffer with glycerol (Irvine Scientific, Santa Ana, Calif.) cryoprotectant. Vials containing 1.8 ml were divided into aliquots and frozen in a programmable freezer (Planar Products, Ltd., Middlesex, England) at the Fertility and Reproductive Health Institute of Northern California. Semen was cooled at −0.5° C per minute to −5° C. After holding for 10 minutes, semen was rapidly cooled at −10° C per minute to −80° C, held for 10 minutes, and stored in liquid nitrogen. Specimens were thawed at room temperature and washed or used for insemination within minutes of thawing. Sperm used for intrauterine

insemination were washed twice with a modified human tubal fluid medium (Irvine Scientific). After the second wash, the sperm pellet was suspended in 0.5 ml of medium and allowed to swim up in a standard procedure.

Standard semen analyses were performed before freezing and before and after washing. Semen analyses were not done in fresh cervical cap insemination cycles. Sperm parameters reported were from the donor's most recent semen analysis. For cervical cap insemination with frozen sperm, samples were evaluated microscopically under high power to assure sperm movement after thawing, but a semen analysis was not done. To estimate postthaw sperm parameters, we multiplied prefreeze sperm parameters by the average decrease in count and motility observed in intrauterine insemination cycles with frozen sperm (prefreeze and postfreeze semen analyses were performed). Azoospermia was defined as the absence of sperm, oligospermia as sperm count $<20 \times 10^6$/ml, and asthenospermia as <30% progressively motile sperm.

Donor selection. Sperm from seven donors was used in this study. American Fertility Society guidelines for selecting and screening donors were followed.[1] We required that donors have two normal semen analyses (count $>60 \times 10^6$/ml, progressive motility >30%, total motility >50%, and >60% normal morphologic features) and excellent sperm recovery after freezing and thawing ($>100 \times 10^6$ actively motile sperm). They then underwent investigation including blood typing, complete blood count, serum chemistry tests, sedimentation rate, and serologic testing for HIV (two tests, 5 to 6 weeks apart), syphilis (Venereal Disease Research Laboratory test), hepatitis profile, cytomegalovirus, and HSV type II antibodies. Urethral cultures for gonorrhea, chlamydia, mycoplasma, and other pathogens were done. HIV testing was also done with a polymerase chain reaction gene amplification method. Donors underwent a thorough history and physical examination, genetic screening, and karyotyping by a geneticist. Donors must have had no genetic predisposition for heritable disease, no more than one sexual partner within the past year, and no history of male sexual partners or alcohol, illicit drug, or intravenous drug abuse. Monthly HIV and other sexually transmitted disease tests were done; this regimen was more frequent and rigorous than recommended.[1]

Data analysis. Statistical analyses were performed with BMDP Statistical Software, Inc. (Los Angeles) and SAS (SAS Institute, Inc., Cary, N.C.). Analysis included Student's *t*-tests, χ^2 tests, life-table calculations, and survival analyses with fixed covariates according to the Cox model. Cycle fecundity or the probability of conception per cycle was calculated by the method of Cramer et al.[18] Because 13 women underwent more than one course of treatment, analyses were performed on courses of treatment rather than on patients. Values are expressed as mean ± SE and range.

Results

Patient characteristics. Fifty-seven women entered the study and underwent 72 courses of treatment. Forty-four women began one, 11 began two, and two began three courses of treatment. In five women the first six cycles did not result in pregnancy and they continued the treatment regimen, with one becoming pregnant. Three were treated for five or six cycles, conceived while off protocol, and returned for a second course of treatment, during which all three conceived. Three conceived while on protocol and returned for a second course of treatment. Of the two women with three courses of treatment, the first did not conceive in 6 months and had a second course of treatment resulting in a spontaneous abortion and a third resulting in a live birth. The second patient had six cycles without pregnancy, conceived while off protocol and had a spontaneous abortion, then conceived while on protocol and had a spontaneous abortion, and again conceived while on protocol and had a live birth.

Women were 32.5 ± 0.5 (range 22 to 42) years old with 5.2 ± 0.6 (range 0.1 to 9.7) years of infertility. Twenty-nine (40.3%) were nulligravid and 36 (50%) male partners had never fathered a child. Female infertility factors included 16 (22.2%) women with ovulatory dysfunction, 20 (27.8%) with endometriosis, 4 (5.6%) with unilateral tubal occlusion or fimbrial damage, and 4 (5.6%) with cervical factor infertility (poor cervical mucus or female antisperm antibodies). Thirty-eight (52.8%) women had no identifiable infertility factor. Forty-five (62.5%) men were azoospermic and 30 (41.7%) had had a vasectomy. Twenty-two of 30 (73.3%) men had attempted reversal of vasectomy and 7 of 8 (87.5%) men underwent varicocele repair but were still unable to conceive.

Outcome. There were 30 conceptions during 198 insemination cycles for a fecundity of 15.2% (Table I). Eight women conceived in nonprotocol cycles. Forty-seven percent ($n = 14$) of conceptions occurred in the first insemination cycle, 77% ($n = 23$) within two cycles, and 83% ($n = 25$) within three cycles. Conceptions resulted in 21 live births and nine spontaneous abortions (six in fresh and three in frozen insemination cycles). Twenty-one conceptions occurred in 102 insemination cycles with fresh sperm (fecundity = 20.6%), and nine conceptions took place in 96 insemination cycles with frozen sperm (fecundity = 9.4%, $p < 0.03$ by χ^2 analysis). Women achieved 20 pregnancies in 146 cycles of

*$p < 0.03$ for fresh versus frozen sperm by χ^2 analysis.

cervical cap insemination (fecundity = 13.7%) and 10 pregnancies in 52 cycles of intrauterine insemination (fecundity = 19.2%, $p = 0.34$). Fecundity was similar in fresh cervical cap insemination (20.3%) and fresh intrauterine insemination (21.2%) cycles ($p = 0.91$) and in frozen cervical cap insemination (7.8%) and frozen intrauterine insemination (15.8%) cycles ($p = 0.28$). Cycle fecundity was significantly greater in fresh than in frozen cervical cap insemination cycles ($p < 0.03$) but was similar for fresh and frozen intrauterine insemination cycles ($p = 0.63$). Ovulation stimulation was performed in 44 (84.6%) intrauterine insemination and 6 (4.1%) cervical cap insemination cycles ($p = 0.000$). There were no ectopic pregnancies, pelvic infections, or complications during the course of the study.

We examined the effect of known female infertility factors on fecundity in women receiving both insemination types (fresh or frozen sperm) and insemination methods (cervical cap insemination or intrauterine insemination, Table II). The greatest fecundity was observed in women with cervical factor infertility (fecundity = 44.4%). This fecundity was significantly greater than that for women without cervical factor infertility ($p = 0.03$). Most women with cervical factor infertility received intrauterine insemination, which was also associated with greater cycle fecundity in this group ($p = 0.01$ for intrauterine insemination vs cervical cap insemination). However, the number of women with cervical factor infertility was very small. Women with no identified infertility factors and women with azoospermic male partners had fecundity similar to that of others. The lowest fecundity was in women with tubal damage.

Life-table estimated cumulative pregnancy rates at 3 months (± SE) were 0.48 ± 0.10 after insemination with frest sperm and 0.22 ± 0.08 after insemination with frozen sperm (Fig. 1, $p = 0.05$ by Breslow analysis, $p = 0.03$ by Mantel-Cox analysis). Three-month estimated cumulative pregnancy rates were 0.55 ± 0.14 for cervical cap insemination with fresh sperm, 0.23 ± 0.10 for cervical cap insemination with frozen sperm, 0.33 ± 0.10 for intrauterine insemination with fresh sperm, and 0.22 ± 0.11 for intrauterine insemination with frozen sperm (Fig. 2). Estimated cumulative pregnancy rates at 3 months were greater for cervical cap insemination with fresh sperm than with frozen sperm ($p = 0.05$ by Breslow analysis, $p = 0.03$ by Mantel-Cox analysis) but similar for intrauterine insemination with fresh versus frozen sperm ($p = 0.57$ by Breslow analysis, $p = 0.57$ by Mantel-Cox analysis).

Survival analyses evaluated the effect of single variables on the probability of conception. Cervical factor infertility ($p = 0.03$) and more extensive adhesions staged according to the American Fertility Society revised 1985 scoring system ($p = 0.04$) were positively associated with pregnancy. Fresh sperm was positively associated with probability of pregnancy in cervical cap insemination and intrauterine insemination cycles ($p = 0.04$) and in cervical cap insemination only cycles ($p = 0.04$). Fresh sperm was not associated with pregnancy in intrauterine insemination only cycles ($p = 0.52$). In addition, intrauterine insemination (vs cervical cap insemination) was not positively associated with pregnancy.

Semen analyses. An average of 262.6 ± 15.7 × 10^6 motile sperm (Volume × Count × Progressive motility/100) were used for fresh cervical cap insemination, 22.7 ± 1.2 × 10^6 for frozen cervical cap insemination, 32.6 ± 3.9 × 10^6 for fresh intrauterine insemination, and 5.6 ± 1.1 × 10^6 for frozen intrauterine insemination. We did not observe a significant association between number of motile sperm inseminated and fecundity in any of the insemination groups by use of *t* tests and survival analyses with fixed covariates (Table III). With freezing, sperm count decreased by an average of 60% ± 5% and progressive motility decreased by 63% ± 4%.

Donors were ranked from highest to lowest fecundity. Only one donor had significantly greater fecundity with fresh (fecundity = 0.30) than with frozen (fecundity = 0.05) insemination cycles ($p < 0.04$). For donors with >10 insemination cycles, there was no difference in fecundity between the three donors with the greatest and the two with the lowest ($p < 0.15$). No donor tested positive for HIV.

Comment

Prospective randomized clinical trials have shown that frozen sperm result in similar cumulative pregnancy rates over a 1-year period (45% to 73%) when compared with those of fresh sperm (53% to 97%) but may have decreased cycle fecundity, as compared with fresh sperm.[8, 11, 12, 17] Studies in which only fresh sperm was used show a fecundity of 15% versus 5% to 11% with frozen sperm.[12, 14, 19-22] Two of three prospective

randomized studies using women as their own controls observed a threefold to fourfold increase in cycle fecundity ($p < 0.001$) with similar 1-year estimated cumulative pregnancy rates for fresh compared with frozen sperm.[11, 12] We observed fecundity similar to that reported in the literature for fresh (20.6%) and frozen (9.4%) insemination cycles and a twofold increase in 3-month estimated cumulative pregnancy rates with fresh sperm compared with frozen sperm. This increased pregnancy rate with fresh sperm occurred in cervical cap insemination cycles but not intrauterine insemination cycles.

Decreases in fecundity and cumulative pregnancies have been attributed to sperm damage during processing and freezing and fewer total motile sperm used per insemination.[15] Such damage may be less important in intrauterine insemination cycles because sperm are deposited beyond the barrier of the cervix and more proximal to the oocyte. Similar fecundity rates for fresh and frozen sperm have been observed for intrauterine insemination and in vitro fertilization, insemination techniques that bypass many of the obstacles sperm must overcome with cervical cap insemination.[23]

Studies have shown that the great majority of patients

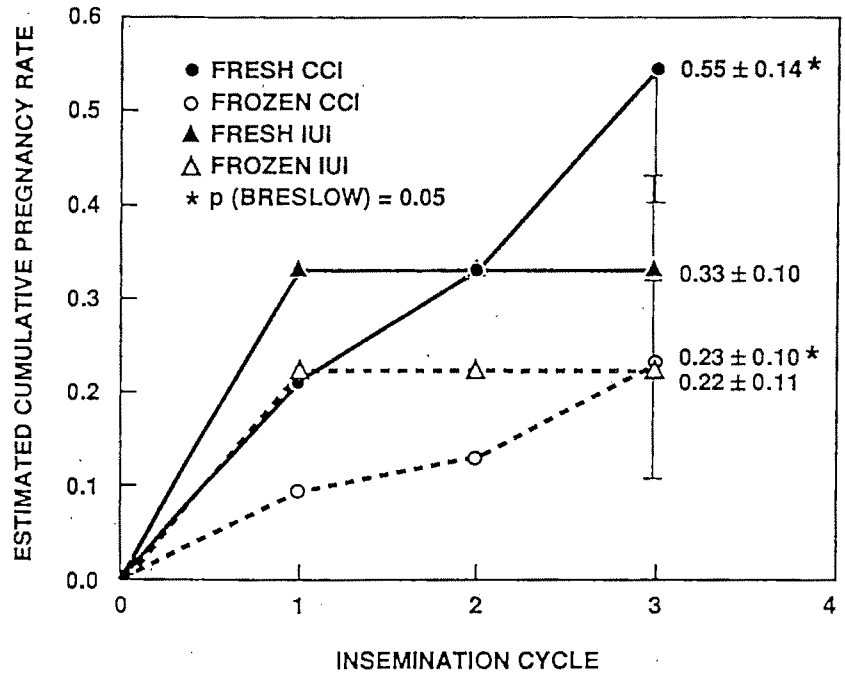

Fig. 2. Estimated life-table cumulative pregnancy rates at 1-month intervals. Estimated cumulative pregnancy rates over 3 months were greater for cervical cap insemination with fresh sperm than for cervical cap insemination with frozen sperm ($p = 0.05$ by Breslow analysis). *Bars* indicate standard error.

Table III. Millions of motile sperm inseminated ± standard error with ranges in conception and nonconception cycles

Insemination type	*Conception cycle*	*Nonconception cycle*	*Significance*
Cervical cap insemination			
Fresh sperm	249 ± 32 (57-514) ($n = 14$)	266 ± 18 (18-621) ($n = 55$)	$p = 0.66$
Frozen sperm	43 ± 7 (20-65) ($n = 6$)	33 ± 2 (4-81) ($n = 71$)	$p = 0.18$
Intrauterine insemination			
Fresh sperm	42 ± 9 (17-87) ($n = 7$)	30 ± 4 (1-91) ($n = 26$)	$p = 0.24$
Frozen sperm	1.2 ± 0.5 (0.7-1.6) ($n = 2$)	6.1 ± 1.2 (0.6-15) ($n = 16$)	$p = 0.18$

who conceive with therapeutic donor insemination do so within six cycles.[10] In this study 83% of conceptions occurred within three insemination cycles and all intrauterine insemination conceptions occurred in the first cycle. Women failing to conceive after three cycles with cervical cap insemination may benefit from several intrauterine insemination cycles. Controlled ovarian hyperstimulation, with clomiphene citrate initially and then with human menopausal gonadotropin, also should be considered since this may increase fecundity further. In clinical practice 9 to 12 months of therapeutic donor insemination may be a sufficient trial before other fertilization methods or adoption is attempted.

Our spontaneous abortion rate of 29% after conceptions with fresh sperm and 33% after frozen were slightly higher than the reported range of 11% to 17%.[10, 15] This may be due to the age and/or infertility status of our patients or to our obtaining serum pregnancy test results at just 2 weeks after insemination.

Increasing age, duration of infertility, pelvic abnormalities, and oligospermia have been associated with significantly decreased therapeutic donor insemination pregnancy rates.[15, 24] The only factors we found to be positively associated with the probability of pregnancy were cervical factor infertility, treated adhesions, and use of fresh sperm. This association with cervical factor infertility was probably due to the successful use of

intrauterine insemination in this group, because women in all of four intrauterine insemination cycles conceived. Increased fecundity with treated adhesions is probably due to increased tubal and ovarian mobility.

Pregnancy rate and fecundity have been positively associated with the number of motile sperm inseminated, and there may be a critical number of sperm required to attain a maximal outcome.[8, 11, 15, 21] Bordson et al.[21] observed similar fecundity rates with intracervical insemination for both fresh and frozen sperm when at least 40×10^6 motile sperm were inseminated. Keel and Webster[8] found that frozen ejaculates with at least 20×10^6 motile sperm had fecundity rate similar to those for fresh ejaculates that contained an average of five times the number of motile sperm. Byrd et al.[15] found that the minimum number of motile sperm required to obtain optimal fecundity occurred in their arbitrarily assigned groups having between 6 and 15×10^6 for intrauterine insemination and between 50 and 100×10^6 for intracervical insemination with frozen sperm. For rates of number of motile sperm inseminated below these values, fecundity was positively associated with number of motile sperm inseminated. We did not find an association between number of motile sperm inseminated and pregnancy, probably because of an inadequate number of cycles. Also, values for sperm parameters in fresh and frozen cervical cap insemination cycles were estimated and therefore are of uncertain accuracy.

The optimal time for insemination with fresh and frozen sperm may be different. Frozen sperm have decreased motility and viability, requiring more careful timing of insemination and perhaps necessitating more inseminations per cycle and increased cost than fresh sperm.[15, 16] In addition, the optimal time for insemination with frozen sperm may be different for intrauterine insemination than for cervical insemination. The highest cycle fecundity with cervical cap insemination with frozen sperm was achieved when inseminations were performed 0 to 10 hours after the LH peak versus 10 to 20 hours with intrauterine insemination.[15] We timed intrauterine insemination and cervical cap insemination with urinary LH home testing and basal body temperature graphs. In addition, women with ovulatory dysfunction had ovulation stimulation with clomiphene citrate with or without human menopausal gonadotropin. Ovulation stimulation allowed more accurate timing of insemination. In studies that compared single and multiple inseminations per cycle with intracervical insemination, fecundity was not affected by the number of inseminations per cycle.[17, 21] However, Byrd et al.[15] found an increase in fecundity when two inseminations per cycle were done with intrauterine insemination and frozen sperm.

Donor retesting for HIV 6 months after sperm donation and freezing is recommended because the virus can be transmitted and is infectious in fresh and cryopreserved sperm.[4] The risks of HIV infection after exposure in therapeutic donor insemination are unknown. In this study no donor tested positive for HIV. In other studies seven women have been reported to be seropositive for HIV after therapeutic donor insemination with an HIV-positive donor.[4, 5] However, women's HIV status was not documented before therapeutic donor insemination cycles. The risk of HIV infection after a single episode of vaginal intercourse with an infected partner is estimated as ≤ 0.002.[3] When the partner is known to be HIV negative and has no history of high-risk behavior, the risk of infection after one episode of unprotected intercourse is estimated to be one in 500,000,000.[5] Using a carefully screened, reliable donor pool and frequent HIV testing with polymerase chain reaction should make the risk of HIV transmission in therapeutic donor insemination with fresh sperm exceedingly remote. Polymerase chain reaction is a highly sensitive test for HIV proviral deoxyribonucleic acid that detects infection earlier than tests for serum HIV antibodies and viral culture.[25]

Fresh sperm is believed to be more effective, thereby requiring less time and cost to conceive than frozen sperm.[9] The eventual percentage of couples conceiving could be similar for fresh and frozen sperm, but frozen sperm requires up to double the time to conceive because the pregnancy rate is less.[13, 14] In this study insemination with fresh sperm resulted in greater cycle fecundity ($p < 0.03$), life-table estimated 3-month cumulative pregnancy rates ($p = 0.05$ by Breslow analysis), and positive association with pregnancy in survival analyses ($p = 0.04$). Nevertheless, given the current medicolegal and political status surrounding the use of fresh sperm, frozen sperm has become almost the universal standard. Therefore the reduced fecundity associated with therapeutic donor insemination with frozen sperm must be recognized in our counseling and management of couples undergoing therapeutic donor insemination.

We acknowledge the assistance and support of Emmet J. Lamb, MD, in the preparation of this manuscript and David Pasta, MS, for his assistance with the statistical analysis.

Discussion

DR. PHILIP E. YOUNG, San Diego, California. There is a great deal of information in this article, but I shall limit my comments to the major issues. (1) Is fecundity, the pregnancy rate per cycle, obtained with fresh semen different from that obtained with frozen semen? Is the difference large enough to be meaningful for patients who undergo three cycles of insemination? (2) Is the answer affected by whether the insemination is done vaginally or directly into the uterus?

The answers to these questions are important because the risk of HIV transmission with proper screening is very small, but it is not zero. If there is a substantial long-term better chance of pregnancy with fresh rather than frozen semen, there may well be a number of couples who would use fresh semen, opting to take the remote chance of HIV transmission to improve the chance of achieving a pregnancy. If, over the duration, the chance of pregnancy were the same for fresh and for frozen semen, it is difficult to imagine that anyone would choose use of fresh semen, regardless of how small the difference in risk of HIV transmission.

The questions addressed in this study have been discussed by many other studies, including one I presented to this society 3 years ago.[1] The major strengths of Dr. Adamson's study are that it was a prospective study and that it included a crossover design in which the subjects were assigned equal numbers of inseminations with fresh or frozen semen with the order randomly determined. This design has not, to my knowledge, been applied to this question before. Randomization is especially important because the group of patients studied was a disparate group, as the group of patients undergoing therapeutic donor insemination always is. Many of his subjects had several other potential causes of infertility.

The weaknesses of this study are as follows: (1) The study deals with a relatively small number of patients: 57 women undergoing 72 treatment cycles of six or fewer inseminations each, giving a total of 198 inseminations. (2) Semen analysis was done only periodically on the donors of the fresh specimens, not with each insemination. Further, semen analysis was not done on thawed specimens used for vaginal insemination. Thus, although the article contains a table comparing sperm counts for both fresh and frozen sperm with both intrauterine insemination and the vaginal inseminations, these counts are often estimated. The assumption of

stability in count is, perhaps, reasonable for clinical decisions but not for scientific analysis. Given these caveats, what answers do the authors provide?

They tell us that when semen is applied to the cervix the cycle fecundity of fresh semen is 20.6% versus 7.8% per cycle for frozen semen, a statistically significant difference. There is also a significant difference in the estimated cumulative probability of pregnancy at 3 months, that for fresh semen being 55% and that for frozen semen being 23%. This is the most meaningful conclusion of the article. When the authors combined the vaginal and intrauterine data, there was also a significant difference between the fresh and frozen groups as one might anticipate since the intrauterine group is relatively small.

When fresh and frozen sperm were compared for intrauterine inseminations alone, there was no significant difference. The authors concluded that in some way a defect present in frozen semen is overcome by the processes involved in intrauterine insemination, a conclusion I believe is not warranted by the data because of the small number of patients studied and the fact that this aspect of the treatment was not randomly assigned. Hence, the authors' discussions of possible reasons why fresh semen does not appear to be better than frozen for intrauterine insemination are quite speculative.

This article supports the conventional wisdom, and the majority of reports in the literature, that the cycle fecundity of fresh semen is substantially better than that of frozen semen. I do not agree that a 3-month evaluation of the cumulative probability of pregnancy is sufficient to assess the efficacy of frozen versus fresh semen. The literature suggests that follow-up extending to 9 or 12 months will often show only minimal differences between the cumulative probabilities of pregnancy for fresh and frozen semen.

It is clear that the use of frozen semen for therapeutic donor insemination is now the standard of care in the United States. Therefore I agree with the authors' final statement that the reduced fecundity associated with therapeutic donor insemination with frozen sperm must be recognized in our counseling and management of couples undergoing therapeutic donor insemination. I personally believe the major variable in the insemination process that affects the pregnancy rate is the total number of motile sperm delivered. I believe that as technology improves and this number increases for frozen semen, the time required to achieve a given cumulative probability of pregnancy with frozen specimens will be decreased.

DR. KENNETH A. BURRY, Portland, Oregon. This is an excellent article. The experience at Oregon Health Sciences University in a prospective comparison of cycle fecundity with fresh and frozen semen is similar to that of the authors. Also similar are our results comparing intracervical and intrauterine insemination. Finally, we believe that when using intrauterine insemination with thawed sperm we also have obtained a cycle fecundity similar to that obtained using fresh semen. Our program therefore uses only quarantined, frozen semen. In your practice now do you still use fresh semen and intensive surveillance for HIV or do you use thawed semen with intrauterine insemination?

DR. ROBERT ISRAEL, Los Angeles, California. The authors have presented a superb, clear, and statistically thorough article. Most of us are using intrauterine insemination for homologous inseminations. Do you think we should go back to using the cervical cap routinely for therapeutic donor insemination, except for women with cervical factor infertility?

DR. ENRIQUE DECASTRO, Portland, Oregon. How does the thawing time affect the sperm? What is the optimum time for insemination after thawing?

DR. ADAMSON (Closing). Dr. Young focused on the difference in fecundity between fresh and frozen sperm. Our study's major strength is that it is a prospective randomized study. We do show a statistically significant difference between fresh and frozen sperm in fecundity and in 3-month cumulative pregnancy rate. These results are consistent with results reported by others in the literature after evaluation of more cycles with much less rigorous design and analysis. The difference in fecundity is especially significant for couples with multiple factors that reduce fecundity. Many couples undergo only three or four cycles of donor insemination; therefore the 3-month cumulative pregnancy rate difference is important in counseling. With fecundity of 0.094, insemination with frozen sperm will take 12 months to obtain the 68% pregnancy rate achieved in 5 months with fresh sperm. Most patients in our practice consider this a meaningful difference and prefer fresh sperm in spite of the risk of acquired immunodeficiency syndrome. This is especially true when this risk is compared with the risks of acquiring hepatitis C or dying of pregnancy complications. We perform exceedingly rigorous screening for infectious diseases to minimize the risk. We currently inform patients of the differences in the risks and benefits between fresh and frozen sperm and use our data to encourage them to undergo more cycles with frozen sperm.

The design of our study does not allow us to draw conclusions on the use of cervical cap compared with intrauterine insemination or on the effect of the number of sperm inseminated. However, our data are consistent with those reported by others that suggest that intrauterine insemination may improve pregnancy rates with frozen sperm. We agree that the total number

of motile sperm delivered is probably the most important controllable variable.

Dr. Burry, we have recently changed our approach and perform one intrauterine insemination per cycle with two "straws" of frozen sperm approximately 12 to 24 hours after a urinary LH surge. Should conception not occur after three cycles, we consider adding 150 mg of clomiphene citrate on cycle days 3 to 7 for three to six cycles and finally recommend using human menopausal gonadotropin for one to three additional cycles. For women failing to conceive after this, we recommend in vitro fertilization, adoption, or child-free living.

Dr. Israel, we use intrauterine insemination when we perform homologous insemination with controlled ovarian hyperstimulation for patients with cervical factor infertility, including poor cervical mucus, antisperm antibodies, and consistently poor postcoital or cervical mucus penetration tests. We also empirically use up to six cycles of intrauterine insemination for partners with abnormal semen analyses. For couples with sexual dysfunction alone we use cap insemination; however, when there is a scheduling difficulty we also use intrauterine insemination of homologous frozen sperm.

Dr. DeCastro, we thaw our specimens at room temperature because this method is convenient and probably as efficacious as any other. We perform the insemination immediately to maximize the number of progressively motile sperm placed in the uterus.

Effect of controlled ovarian hyperstimulation on pregnancy rates after intrauterine insemination

Sheila J. DiMarzo, PhD, Joseph F. Kennedy, MD, Philip E. Young, MD, Stephen A. Hebert, MD, Dianne C. Rosenberg, MD, and Benito Villanueva, MD
San Diego, California

OBJECTIVE: Our objective was to evaluate the effect of controlled ovarian hyperstimulation on pregnancy rates after intrauterine insemination of washed husband's sperm.
STUDY DESIGN: In a private practice setting at the Infertility, Gynecology, and Obstetrics Medical Group in San Diego, 79 treatment programs included intrauterine insemination during natural cycles, 195 included clomiphene stimulation, and 53 had human menopausal gonadotropin stimulation. Pregnancy rates and monthly fecundabilities were calculated by life-table analysis and compared by the Z test.
RESULTS: By life-table analysis the cumulative probability of pregnancy after intrauterine insemination with no ovulation induction is 21.0% after six cycles with a monthly fecundability of 3.4%. With clomiphene the pregnancy rate is 32.7% with a monthly fecundability of 6.1%, and with human menopausal gonadotropin the pregnancy rate is 60.7% with a monthly fecundability of 13.0%. The human menopausal gonadotropin group had a significantly higher pregnancy rate and monthly fecundability as compared with the other two groups. There were no differences between the no-stimulation and the clomiphene groups.
CONCLUSIONS: Human menopausal gonadotropin stimulation results in a significantly higher pregnancy rate and monthly fecundability after intrauterine insemination as compared with no stimulation or clomiphene use. (Am J Obstet Gynecol 1992;166:1607-13.)

Key words: Controlled ovarian hyperstimulation, intrauterine insemination, pregnancy rates

Intrauterine insemination with washed husband's sperm has been used as a treatment for various forms of infertility for many years in spite of the fact that questions about its effectiveness and rationale for use have abounded in the literature.[1] As techniques for sperm preparation improved,[2] largely as a result of in vitro fertilization (IVF) protocol developments, increased pregnancy rates have been reported,[3-5] whereas other reports indicate no such increases.[4, 6] Consequently, clinical use of this procedure has continued in spite of the lack of adequately controlled studies demonstrating its efficacy.

Controlled ovarian hyperstimulation followed by intrauterine insemination with husband's washed sperm has also been used with increasing frequency,[7-10] particularly in situations where a stimulation cycle fails to meet the criteria to proceed with a gamete intrafallopian transfer (GIFT) or IVF cycle.[11] Considering a patient's investment in terms of cost, time, and emotional stress it is often preferable to offer intrauterine insemination, assuming that at least one fallopian tube is patent, rather than to completely cancel the style. The success of these treatments has prompted some clinicians to recommend a trial of a few months of intrauterine insemination with controlled ovarian hyperstimulation before GIFT or IVF for patients with patent tubes.[10, 12, 13]

Within our practice patients with varying diagnoses have been offered intrauterine insemination for several years. Some received ovulation induction medications to correct ovulatory disorders and others were hyperstimulated as an empiric treatment, usually after the failure of intrauterine insemination without stimulation. This article is a retrospective study comparing pregnancy rates in three treatment groups of patients: no ovarian stimulation followed by intrauterine insemination, clomiphene treatment followed by intrauterine insemination, and human menopausal gonadotropin (hMG) hyperstimulation followed by intrauterine insemination. Individual patient couples often fell into two or all three treatment groups for one or more cycles as their workup progressed. In all cases intrauterine insemination was done with washed husband's sperm. Pregnancy rates are compared between the three treatment groups, and the patient treatment groups are described in respect to patient age, number of insem-

ination cycles per treatment group, number of motile sperm used for insemination, and number of inseminations per treatment cycle.

Material and methods

Couples who had undergone extensive infertility evaluations and treatments were offered intrauterine insemination of washed husband's sperm as a treatment option. They were eligible to participate if the male had any motile sperm and if the female had at least one open fallopian tube and ovulated either spontaneously or with medication. Data include all intrauterine insemination cycles with husband's washed sperm that took place within our practice in the years 1988 through 1990. If a couple in the study had insemination cycles in a prior year, those cycles were included. Many of the patient couples were evaluated for their infertility within our practice, but some were referred specifically for insemination with washed husband's sperm.

A treatment program is defined as a series of monthly cycles of intrauterine insemination with washed husband's sperm for the purpose of achieving a pregnancy. Some ovulatory cycles were natural, meaning no stimulation medications were used, some cycles were stimulated with clomiphene, and others were stimulated with hMG. Ovulation was pinpointed by home urinary luteinizing hormone (LH) testing and, occasionally, with serial ultrasonographic examinations and hormone assays measuring estradiol, progesterone, and LH (Diagnostic Products, Los Angeles). Inseminations were usually performed on the day after the LH surge when there was one insemination and on the day of the LH surge and the day after if two inseminations took place. If clomiphene was given, the dosage ranged from 25 to 200 mg/day (most commonly 50 mg/day) for 5 days in the early follicular phase. If hMG was used, injections usually began on cycle day 3 with one or two ampules and continued until day 8, at which time hormonal and ultrasonographic measurements were used to individualize the protocol to achieve the desired results. Patients on the hMG protocol received 10,000 IU of human chorionic gonadotropin when hormonal values and ultrasonographic measurements indicated mature follicles. Inseminations were timed for 36 hours later (one insemination) or 12 and 36 hours later (two inseminations). Many patients started with one treatment protocol and switched to a second or third protocol if pregnancy was not achieved. Typically, intrauterine inseminations were first done in the absence of stimulation unless specific ovulatory disorders were found. Patients not achieving pregnancy often were switched to clomiphene treatment and finally to hMG treatment in hopes of initiating a pregnancy.

Semen specimens were collected by masturbation into a sterile plastic specimen container and delivered to the laboratory within 1 hour of collection. The specimen was first analyzed for sperm count and motility with a computerized semen analysis system (CellSoft, Cryo Resources, New York) and then mixed with two to three volumes of Sperm Capacitation Medium (Irvine Scientific, Irvine, Calif). The diluted semen was centrifuged at 900 rpm for 7 minutes, the supernatant was removed, and the resulting pellet was resuspended in 2 ml of medium. After recentrifugation at 900 rpm for 4 minutes, the supernatant was removed and the pellet was resuspended to 0.3 ml with medium. A final analysis was done to determine total motile sperm for insemination, and the medium containing the washed sperm was drawn up into the transfer catheter and delivered to the examination room for insemination. The transfer catheter was a 5½-inch sterile polyethylene 3½Fr Tomcat catheter (Sherwood Medical, St. Louis) attached to a 1 ml disposable syringe. With the patient in the lithotomy position and a speculum in place, the transfer catheter containing the washed sperm was passed gently through the cervical canal and into the uterine cavity. The specimen was expelled from the catheter, and the catheter was removed. The patient rested for 10 to 15 minutes and then resumed normal activity.

cles, clomiphene-stimulated cycles, and hMG-stimulated cycles were made by the statistical methods described in detail by Cramer et al.[14] Life tables were constructed and monthly fecundabilities were determined. The Z test was used to compare the monthly fecundabilities, pregnancy rates, and the other variables discussed.

Results

For the treatment group receiving intrauterine insemination without ovulation induction, there were six pregnancies among 79 treatment programs. These 79 treatment programs included a total of 186 insemination cycles, for an average monthly fecundability of 3.2%. For the treatment group receiving intrauterine insemination after clomiphene administration, there were 31 pregnancies among 195 treatment programs. These 195 treatment programs included a total of 540 insemination cycles, for an average monthly fecundability of 5.7%. For the treatment group receiving intrauterine insemination after hMG stimulation there were 13 pregnancies among 53 treatment programs. These 53 treatment programs included a total of 104 treatment cycles, for an average monthly fecundability of 12.5%. By Z test analysis the differences in monthly fecundabilities between no ovulation induction versus hMG stimulation is significant ($p = .005$) as is that between clomiphene administration and hMG stimulation ($p = 0.02$). The monthly fecundability for intrauterine insemination with clomiphene administration is not statistically different from that after no ovulation induction.

The life-table analysis for the cumulative probability of pregnancy after intrauterine insemination for each of the treatment groups are shown in Tables I, II, and III. In Table I the cumulative probability of pregnancy following IUI with no ovulation induction is 21.0% after six insemination cycles. This life-table analysis estimates the monthly fecundability as 3.4% with a 95% confidence interval of 0.7% to 6.2%. In Table II the cumulative probability of pregnancy after intrauterine insemination and clomiphene administration is 32.7% after six insemination cycles. This life-table analysis estimates the monthly fecundability as 6.1% with a 95% confidence interval of 3.9% to 8.2%. In Table III the cumulative probability of pregnancy after intrauterine insemination after hMG stimulation is 60.7% after six insemination cycles. The life-table analysis estimates the monthly fecundability as 13.0% with a 95% confidence interval of 5.9% to 20.1%. By Z test analysis the differences in monthly fecundabilities between no ovulation induction versus hMG stimulation is significant ($p = 0.006$) as is that between clomiphene administration and hMG stimulation ($p = 0.026$). The monthly fecundability for intrauterine insemination with clomiphene administration is not statistically different from that after no ovulation induction. The differences between the cumulative probability of pregnancy after six insemination cycles for intrauterine insemination with no ovulation induction versus hMG stimulation is significant ($p < 0.001$), as is that between clomiphene administration and hMG stimulation ($p < 0.001$). The cumulative probability of pregnancy after six insemination cycles for intrauterine insemination with clomiphene administration is not statistically different from that after no ovulation induction.

To determine if there was some variable that was different among the three treatment groups which might explain these differences in pregnancy rates, several factors were investigated, as shown in Table IV. This table indicates that in terms of the age of the woman, the number of insemination cycles per treat-

Pregnant	1.2 ± 0.4	1-2	1.4 ± 0.5	1-2	1.7 ± 0.5	1-2
Not pregnant	1.4 ± 0.5	1-3	1.4 ± 0.5	1-4	1.7 ± 0.5	1-3

ment program, the number of motile sperm per insemination cycle, and the number of inseminations per treatment cycle there were no differences between the three treatment groups. In addition, the percent of patients in each treatment group who had never been pregnant (before starting the treatment program) was not different (51% for intrauterine insemination without ovulation induction, 51% for intrauterine insemination after clomiphene administration, and 46% for intrauterine insemination after hMG stimulation). Table IV also shows that there is no difference in any of these variables between the pregnant and nonpregnant patients within each of the three treatment groups.

Each treatment group consisted of a very diverse patient population. Some patient couples had idiopathic infertility, whereas others had one or more male and/or female infertility factors present. The distribution of the numbers of male or female infertility factors did not differ between the treatment groups nor did it differ between the pregnant and nonpregnant patients within each group.

The treatment group that had intrauterine insemination after hMG stimulation had the highest overall pregnancy rate, although many of these patients (38%) had undergone an average of 4.6 ± 3.1 (range 1 to 11) insemination cycles with no ovulation induction or clomiphene administration before hMG stimulation. Of the hMG-stimulated patients who achieved a pregnancy, 54% had undergone an average of 3.6 ± 3.5 (range 1 to 11) insemination cycles in one or both of the other two treatment groups.

Comment

This retrospective study of patient couples receiving intrauterine insemination treatment with husband's washed sperm clearly demonstrates a significantly increased pregnancy rate and monthly fecundability after controlled ovarian hyperstimulation with hMG as com-

pared with the pregnancy rates in the absence of ovulation induction or with the use of clomiphene. These differences are not due to differences in the patient populations because they are very similar in terms of the age of the female patient, her gravidity, the number of infertility factors, the number of intrauterine insemination treatment cycles, the number of motile sperm per intrauterine insemination cycle, and the number of inseminations per intrauterine insemination cycle. If anything, the study design should have skewed the results toward lower pregnancy rates with intrauterine insemination after hMG stimulation because a large number of these patient couples had already failed with intrauterine insemination in the absence of ovulation induction or with clomiphene administration. It is of interest to note that clomiphene use did not increase the pregnancy rate after intrauterine insemination in this study, a finding supported by Martinez et al.[15]

In our clinical practice we continue to offer intrauterine insemination with washed sperm for treatment in patients with a variety of infertility factors. In some cases the rationale is straightforward, such as with oligospermia or cervical factor. In other cases, such as ovulation disorders or endometriosis, the treatment is more empiric. The addition of controlled ovarian hyperstimulation to the intrauterine insemination protocol is clearly therapeutic in the presence of ovulatory disorders and empiric in most others. This study supports our clinical approach and, in fact, has led us to consider hMG stimulation sooner in a patient's treatment, especially after four to six failed intrauterine insemination cycles with clomiphene administration. This clinical approach and the finding of a limited success after four to six treatment cycles is supported in the literature.[11, 16, 17]

Drawbacks to the use of hMG stimulation before intrauterine insemination include the relative cost of a treatment cycle in view of the medication costs, the necessity of increased monitoring by hormone assays and ultrasonographic measurements, and the risks of ovarian hyperstimulation and multiple gestation. Although the cost of an hMG-stimulated intrauterine insemination cycle is expensive, it is still substantially less expensive than an IVF or GIFT procedure. The medical risks of hMG stimulation can be minimized by very careful preovulatory monitoring of the changes in follicle size and number and the increase in hormonal levels. Consequently, hMG stimulation followed by intrauterine insemination appears to be a reasonable treatment approach before IVF or GIFT treatment for many patients.[11, 12]

Recent literature reviews have carefully examined the rationale and success of this treatment approach.[13, 18] Explanations for a higher pregnancy rate for empiric hMG therapy and intrauterine insemination include the opportunity for increased gamete density at the site of fertilization and the potential correction of subtle ovulatory disorders.

We thank Marda Levy, Denise Wiedman, Dina Ashmead, and Jackie Post for their technical expertise and data collection assistance.

Discussion

DR. KENNETH A. BURRY, Portland, Oregon. Dr. Villanueva and his colleagues have retrospectively reviewed their clinical experience of 253 treatment programs from 1988 through 1990 in which intrauterine insemination was performed. Their conclusion is that performing this procedure after hMG stimulation yields a significantly higher pregnancy rate, or monthly fecundability, as compared with intrauterine insemination after no ovulation induction or clomiphene treatment.

They divided the treatment programs into three groups: (1) intrauterine insemination in a spontaneously ovulatory cycle, (2) intrauterine insemination after clomiphene citrate stimulation, and (3) intrauterine insemination after hMG stimulation. These empiric treatment regimens were used for multiple infertility factors, both male and female. Many of the couples themselves had multiple factors contributing to their infertility.

Intrauterine insemination with and without a male factor has also been used empirically for the treatment of multiple factors causing infertility. The literature gives us a mixed message concerning the efficacy of this therapy. Kerin et al.[1] claim that intrauterine insemination was superior to coitus in couples with impaired semen quality. Cruz et al.[2] found it superior to intrauterine intracervical insemination in male factor infertility. On the other hand, te Velde et al.[3] showed that intrauterine insemination was no better than coitus for male factor; however, it was efficacious in women with cervical factor. A larger study by Kirby et al.[4] of 285 couples compared 600 cycles of intrauterine insemination with 505 cycles of coitus timed by an LH surge. They found no benefit to intrauterine insemination except for severe male factor.

GIFT and IVF are currently used as a last resort by many couples with long-standing infertility. These are expensive technologies with relatively low probability of pregnancy. Welner et al.[5] reported a significant pregnancy rate in 97 couples who received hMG before proceeding to IVF. Many centers are currently offering ovarian hyperstimulation and intrauterine insemination as an option before these assisted reproductive technologies.

Empiric ovulation induction in ovulatory women has been used the treatment of unexplained infertility or conditions associated with low fecundability, such as endometriosis. Deaton et al.[6] reported an increase in cycle fecundity in women treated with clomiphene and intrauterine insemination. Martinez et al.[7] however, saw an increased pregnancy rate with intrauterine insemination only and not with clomiphene. The experience with hMG and intrauterine insemination is more consistent. Dodson et al.[8] reported their experience with hMG and intrauterine insemination in 1987. They showed cycle fecundities of 0.17 for endometriosis, 0.29 for cervical factor, and 0.19 for idiopathic infertility. The editorial comment at the end of their article is worth repeating: "The decision to publish this controversial manuscript has been made with the intent of stimulating debate. The referees feel strongly that, before advocating intrauterine insemination during hMG-stimulated cycles, a prospective controlled study with critically evaluated infertile patients is mandatory. The advocating of this essentially empiric therapy cannot be supported by the rather meager retrospective data presented. The authors agree that they cannot state that this approach is effective therapy but have reported their observed cycle fecundity with its use. Clinicians should be discouraged from applying this therapy until controlled prospective studies can support this approach." This year, Chaffkin et al.[9] reported on 322 couples observed for 751 cycles. They found that hMG and IUI were more efficacious than either modality alone. Although their study reviewed more patients than previous studies, this was another retrospective evaluation of clinical experience. Dodson and Haney[10] reviewed the literature and reported in *Fertility and Sterility*. Their concluding sentence reads, "When the relatively low direct and indirect costs of controlled ovarian hyperstimulation and IUI [intrauterine insemination] are considered, acknowledging the lack of prospective, controlled studies, this procedure appears to be at least as cost-effective as GIFT and IVF."[10]

The conclusions by Dr. Villanueva are consistent with the majority of the literature on this subject. The weakness in the article is that it is another retrospective evaluation of clinical experience. Another concern in the interpretation of their results is the multiple etiologies for infertility in their patient population.

Endometriosis is associated with low fecundability. Ovulatory disorders are associated with a near-normal fecundability when appropriately treated. Male factor infertility is a broad category, and the number of normal motile cells available for insemination is important. Therefore variations in patient populations between groups within a study, as well as between studies, may lead to a significant bias of results.

I have these questions for Dr. Villanueva: (1) You state there are no differences between the three groups. However, I see that 62.3% of the no-ovulation induction group had endometriosis compared with 40.3% of the clomiphene group and 22% of the hMG group. Do you think endometriosis has an impact on the differences in pregnancies among these three groups? (2) Similarly,

the no-induction group had 41.6% of couples with normal male factor compared with the clomiphene group with 59.7% and the hMG group with 66% normal male factor. Was this not significant? (3) On the basis of your experience, what are your current recommendations for management of unexplained infertility or endometriosis in patients with long-standing infertility?

Dr. Simon Henderson, San Francisco. To do intrauterine insemination or not to do it, that is the question. This article does not really answer the question, a question that begs to be answered. Dr. Villanueva, can you tell us your pregnancy rates for clomiphene and gonadotropin treatment without intrauterine insemination? This information would help us approach an answer to the question of whether intrauterine insemination is a necessary part of the treatment.

Dr. Miles Novy, Portland, Oregon. I echo Dr. Burry's comment about the need for prospective controlled studies. It is imperative that in evaluating the efficacy of these methods we compare fairly large groups that have comparable causes of infertility. Dr. Villanueva, an hMG–intrauterine insemination cycle can cost ≥$2000 by the time you add up the costs of the drug and the estradiol and ultrasonographic monitoring. The objective of treatment in these women is to prevent severe ovarian hyperstimulation and to obtain a limited number of follicles, maybe two or three. This objective is quite different from that with hyperstimulation for IVF. This milder effect is frequently achieved with 100 or 150 mg of clomiphene per day and a simple monitoring regimen with a total cost of a few hundred dollars. Would you comment on costs? Finally, Dr. Villanueva, please tell us more about the idiopathic infertility group. It seemed to me from your presentation that there were only 11 patients with idiopathic infertility, that only two were in the hMG group and neither became pregnant.

Dr. Donald Smith, Seattle, Washington. Did you use progesterone supplementation in the luteal phase for your hMG patients?

Dr. Villanueva (Closing). Dr. Burry, thank you for your evaluation. I repeat that we found no statistical difference in the probability of pregnancy between these groups irrespective of their infertility cause. Also, in the no-stimulation group, a group that had a higher percentage of patients with endometriosis, there was also a higher percentage of pregnancies in patients with that diagnosis. The difference was not statistically significant. We now first offer our patients with long-standing infertility intrauterine insemination without ovulation induction. We still use clomiphene stimulation empirically for a short time, perhaps four or six cycles. Then, rather than continuing or moving on to the admittedly more expensive and complicated IVF or GIFT, we offer hMG stimulation with intrauterine insemination.

Dr. Henderson asked whether we have data on cycles with hMG clomiphene stimulation without intrauterine insemination. Unfortunately, I have none at this time.

Dr. Novy, we are very mindful of the cost. I agree with you and with Dr. Burry about the need for a prospective study. Until this is done, these questions will be open to argument.

Dr. Smith, we do not use progesterone supplements.

Percutaneous umbilical blood sampling: Results from a multicenter collaborative registry

Durlin E. Hickok, MD, MPH,[a] Marlin Mills, MD,[b] and the Western Collaborative Perinatal Group

Seattle, Washington, and Phoenix, Arizona

Percutaneous umbilical blood sampling has become an important diagnostic tool in the evaluation of fetal health. Although recent reports have established the safety of this procedure, most have arisen from single centers with extensive experience. The Western Perinatal Collaborative Group has maintained a continuous registry of percutaneous umbilical blood sampling performed at the 13 member institutions for the years 1986 through 1990. During this period 302 procedures were performed. Primary indications for percutaneous umbilical blood sampling included Rh and non-Rh isoimmunization, intrauterine growth retardation, nonimmune hydrops, fetal anomalies, immune thrombocytopenia purpura, and rapid fetal chromosome analysis. Percutaneous umbilical blood sampling was successfully performed in 93.7% of cases with a sample withdrawn by a single puncture in 80.5% of attempts. In the majority of cases a 22-gauge needle was used. Postprocedural fetal death resulted in six cases (2.1%) and was most often associated with fetal anomalies or an abnormal karyotype. In conclusion, evaluation of the fetal state by percutaneous umbilical blood sampling is a safe and easily performed procedure, as demonstrated by a collaborative multicenter study. (Am J Obstet Gynecol 1992;166:1614-8.)

Key words: Percutaneous umbilical blood sampling, fetal anomalies, Rh isoimmunization

Percutaneous umbilical blood sampling has become an increasingly more important and frequently performed diagnostic procedure in evaluating fetal health.[1-3] This relatively new technology has also allowed more direct access to the fetus for treatment in conditions such as Rh isoimmunization.[4]

Although fetal bradycardia and uterine irritability are recognized transient side effects of percutaneous umbilical blood sampling,[5] serious complications such as fetal death appear to be quite uncommon. The safety of the procedure, however, has largely been established from studies originating from single centers with extensive experience of only a few operators.

As tertiary level perinatal centers in the United States have greatly increased over the last decade, invasive obstetric procedures are now performed at a large number of locations, quite in contrast to the more centralized experience reported in other countries.[6-8] We conducted a multicenter investigation to assess the safety of the procedure.

From the Center for Perinatal Studies, Swedish Hospital Medical Center and Departments of Epidemiology and Obstetrics and Gynecology, University of Washington,[a] and the Good Samaritan Medical Center.[b]

Presented at the Fifty-eighth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Ashland, Oregon, September 9-12, 1991.

Material and methods

The Western Perinatal Collaborative Group is a nonprofit research organization that maintains a registry of invasive obstetric procedures performed at its 13 member institutions. Each institution performed percutaneous umbilical blood sampling by its own method, and a protocol for the procedure was neither developed nor suggested. During the time period of 1986 through 1990, a total of 302 procedures were attempted for diagnostic purposes at six of the 13 institutions. Data were collected on standardized forms and included information regarding indications for the procedure, technical details, ultrasonographic findings, tests performed, procedure-related complications, and perinatal outcome. For the purpose of common reporting, we used 3 days after the procedure as the definition of an intrauterine death. Statistical analysis was performed with the Statistical Program for the Social Sciences.

Results

During the study period, 302 percutaneous umbilical blood sampling procedures were attempted between 16 and 39 gestational weeks for a variety of indications (Table I). The most frequent reasons included Rh isoimmunization, idiopathic thrombocytopenia, nonimmune hydrops, fetal anomalies, and idiopathic thrombocytopenia purpura. Of the 302 procedures, 283 were accomplished, for a success rate of 93.7%.

The procedure was performed most frequently with a 22-gauge needle (81.6% of cases) and next most commonly with a 20-gauge needle (15.6% of cases). A 25-gauge needle was used in <3% cases (Table II). The placenta was located anteriorly in 65.5% of cases and posteriorly in 30.2%. In <5% of percutaneous umbilical blood sampling was the placenta fundal or a previa. Cord sampling was performed by an approach next to the placental insertion site in 89.6% and adjacent to the fetus or in a free loop in approximately 10% of cases. Antibiotic treatment of the mother was not routinely used at any center. During or after the procedure tocolytic agents were used in 33.0% of cases.

Immediate procedural complications occurred infrequently, with only a single case leading to immediate delivery due to a prolonged bradycardia that, at the time of cesarean section, was found to be caused by an inadvertent cord laceration. Transient streaming of blood from the cord was common (89.4%), but it persisted for longer than 1 minute in only 10.6% of cases (Table III). Fetal heart rate changes were infrequent, occurring <7% of the time.

More severe complications leading to fetal death within 3 days of the procedure occurred in six cases (2.1%). Four of the six cases were performed for fetal anomalies and the remaining two for severe Rh isoimmunization (Table IV). In one case of multiple anomalies, a karyotype of trisomy 18 returned after fetal death had occurred.

Table I. Primary indication for percutaneous umbilical blood sampling (N = 302)

Indication	*No.*
Rh isoimmunization	65
Intrauterine growth retardation	45
Non-Rh isoimmunization	44
Nonimmune hydrops	31
Multiple anomalies	22
Neural tube defects	21
Idiopathic thrombocytopenic purpura	20
Abnormal amniocentesis	12
Other*	42

*Includes (<10 each) cardiac malformations, congenital infections, pleural effusions, fetal distress, alloimmune thrombocytopenia, hemoglobinopathies, metabolic disorder risks.

Table II. Procedural characteristics (n = 283)

Characteristic	%
Needle size	
20 gauge	15.6
22 gauge	81.6
25 gauge	2.8
Placental location	
Anterior	65.5
Posterior	30.2
Fundal	4.0
Previa	0.4
Location of insertion	
Placental	89.8
Fetal	4.3
Free loop	5.9
Use of tocolytics	
Yes	33.0
No	67.0

Comment

Our results from a multicenter collaborative registry support the safety and effectiveness of percutaneous umbilical blood sampling. The indications for the procedure in this collaborative registry are similar to those reported in the literature, with the exception of Rh and nonisoimmunization being two of the three most common primary indications.[1, 2] This may reflect differences in the referral patterns and a relatively more aggressive approach to the patient with a high titer indirect Coombs' test of institutions participating in this study. The direct determination of fetal disease severity through hematologic (rather than amniotic fluid testing) and the potential elimination of serial amniocentesis in mothers with an antigen-negative fetus are important advantages of percutaneous umbilical blood sampling. Forty-five procedures were done for severe intrauterine growth retardation. This is an important indication for percutaneous umbilical blood sampling, as 17% of severely growth retarded fetuses were found to have chromosomal anomalies in a recent series by Bilardo and Nicolaides.[9]

The majority of cases in this study were performed with a 22-gauge needle, which is similar in size to that described by others.[8, 10] In one of the largest series to date, however, Daffos et al.[6] universally used a 20-gauge needle with a very low reported complication rate.[6] Few data exist relating procedural complications to needle size, and to our knowledge, no randomized trials addressing this question have been performed.

An anterior placental location site was noted in 65.5% of our cases, which is in agreement with results reported by Orlandi et al.[7] The investigators in our series obtained samples from the cord adjacent to the placenta in 89.9% of cases and from a free loop or near the fetus in the remaining 10.2% of cases. Sampling sites were at the placental cord origin in 63.5% of 96 cases reported by Weiner[10] and 72.2% of 322 cases described by Boulot et al.[8]

The duration of blood streaming from the cord and fetal heart rate changes after sampling have been examined as potential markers for procedural complications. We found bleeding for longer than 1 minute from the cord puncture site in 10.6% of cases. In one case an immediate cesarean section was performed

Table III. Procedural complications (n = 283)

	%
Duration of streaming	
<1 min	89.4
≥1 min	10.6
Fetal heart rate change	
None	93.5
Bradycardia	5.8
Tachycardia	0.7

Table IV. Fetal death within 3 days of procedure

Case No.	*Indication*	*Gestational age (wk)*	*Karyotype*
1	Encephalocele	22	ND
2	Nonimmune hydrops	30	Normal
3	Multiple anomalies, fetal distress	23	ND
4	Multiple anomalies	27	47 ± 18
5	Rh isoimmunization	32	ND
6	Rh isoimmunization	24	ND

ND, Not done.

where a small cord laceration was found. No apparent adverse neonatal outcome resulted. This figure is well within the range of 6% to 13% described by others.[6, 11] Our 5.8% rate of transient bradycardia after percutaneous umbilical blood sampling was also similar to the 3% to 12% described by others.[6, 10, 11] Although cord hematomas and amnionitis have been described in other series, we did not encounter either of these complications.

Unexpected fetal death after a percutaneous umbilical blood sampling procedure is clearly the most serious of all potential complications. This risk may be modified by a number of factors including the severity of fetal disease at the time of the procedure, the intrauterine natural history of the disease for which the fetus is being tested, the gestational age at the time, and the experience of the operator. Intrauterine death rates may be expected to vary from center to center, depending on the above considerations. For example, the fetus with hydrops or an autosomal trisomy has a poor intrauterine prognosis even without the potential added risk associated with the diagnostic procedure. In addition, gestational age at the time of testing may modify the direct risk of the procedure[7] and limit therapeutic options. For instance, a fetus of advanced gestational age may be delivered after a procedural complication and treated in the nursery. In contrast, the option of delivering a very immature fetus would not exist and an intrauterine death may be more likely.

Although operator experience is undoubtedly important with respect to the safety and effectiveness of diagnostic procedures such as percutaneous umbilical blood sampling, it has been argued that it should only be performed at large centers with extensive and continuing experience.[8] Reports addressing this question, however, have been mixed. Boulot et al.[8] found a rate of fetal death in utero of 1.9% in a report of 322 percutaneous umbilical blood samplings, performed in 277 pregnancies. All complications occurred in the first 30 procedures performed by each operator and none in the subsequent 210 procedures. In a study of 500 percutaneous umbilical blood sampling procedures performed between 12 and 21 weeks by a single operator, Orlandi et al.,[7] to the contrary, found no relationship between experience and the rate of fetal loss. As many fetal deaths were encountered in the first 100 procedures as in the last 100 in the series.

Our intrauterine fetal death rate of 2.1% compares favorably with reports of others.[6-8] With the low frequency of fetal death and clinically and demographically dissimilar populations, statistical comparison of our study with others would not be meaningful. Four of the intrauterine deaths in our series were associated with fetal anomalies or chromosomal aneuploidies. The remaining two fetal deaths were complicated by Rh isoimmunization at 24 and 32 weeks. No immediate complications were noted in either Rh isoimmunization case and causes for intrauterine deaths were not apparent. It could be argued, however, that the 32-week gestation complicated by Rh isoimmunization could potentially have survived had the complication been immediately recognized.

In conclusion, the results from this multicenter study of 283 percutaneous umbilical blood sampling procedures performed at six institutions compare favorably with reports from other centers with respect to procedure-related complications and intrauterine deaths. Percutaneous umbilical blood sampling is a safe and effective procedure that offers wide clinical application for disease diagnosis and treatment in the fetus.

We thank Kathyrn A. Hollenbach, PhD, Rosalee W. Zingheim, RN, MN, and Michelle A. Williams, ScD, for their help in analyzing the data.

Discussion

DR. RUSSELL K. LAROS, JR., San Francisco, California. Percutaneous umbilical blood sampling has become an important part of our diagnostic and therapeutic armamentarium. Issues currently being debated include indications, risks, and who should be performing the procedure. Because of concerns about misuse, the California State Department of Health is currently promulgating rules and regulation aimed at controlling how, why, and where it will be done. Although the state's motivation is patient protection, I believe we should resist this degree of governmental control of medical practice. The data presented by Dr. Hickok and his colleagues are important in that they address the issues of safety and indications in a multiinstitution setting.

Dr. Hickok has told us about 302 percutaneous umbilical blood sampling procedure attempted at six institutions, thus providing us with one of the largest collective experiences reported to date. He has carefully described indications, methodology, and outcome. I do have six comments or questions that should further clarify his data. (1) Your abstract and Material and methods section imply that 13 institutions contributed cases to the study. It appears to me that only six of the 13 really contributed. Is this correct? (2) How many operators were actually performing percutaneous umbilical blood sampling? Because of the intense interest in the issue of the relationship between operator experience and outcome, please tell us about the frequency of fetal loss and failed procedures as related to operator experience. (3) My arithmetic indicates that the six fetal losses all occurred in cases of successful percutaneous umbilical blood sampling (i.e., 6/283); is this a correct interpretation? If so, the lack of mortality in the unsuccessful cases is reassuring as we all worry about the fetal consequences of multiple, unsuccessful "sticks." (4) Could you explain the reasons for percutaneous umbilical blood sampling rather than amniocentesis in the 21 cases of neural tube defects? Were these cases too far along in gestation to get the same data with the safer procedure? (5) Dr. Hickok is aware of our approach to the delivery of patients with idiopathic thrombocytopenic purpura. Did the information obtained in the 20 cases of idiopathic thrombocytopenic purpura influence the route of delivery in any case? and (6) Finally, in your opinion, how many percutaneous umbilical blood sampling procedures per year per operator are required to maintain proficiency?

I congratulate Dr. Hickok and associates for reporting this important experience. The issue of operator proficiency is especially critical as we consider how to train perinatologists in this technology.

DR. JULIAN T. PARER, San Francisco, California. Dr. Hickok, can you call a procedure with a mortality of 2% a safe procedure? In a day when the overall perinatal mortality is <2%, I believe this is a high rate of mortality. Acknowledging that not all of these deaths are due to the procedure, I would conclude that we should reserve cordocentesis for grave indications and I think you probably agree. We cannot agree on some of your indications, however. One is the use of cordocentesis for early diagnosis of fetal blood type in cases of red cell isoimmunization. It seems to me that because amniocentesis has a mortality of almost zero, and cordocentesis is between 1% and 2%, it is better to use serial amniocenteses as an initial approach to rule in or out severe isoimmunization, rather than to expose the fetus to the risk of cordocentesis.

DR. JACK R. LAMEY, Seattle, Washington. Dr. Hickok, I agree that it is very important for the operator to be very experienced. However, another point that I think is very important was not brought out. If the ultrasonographer is not capable and experienced, the operator is placed at a marked disadvantage.

DR. PETER WATSON, Portland, Oregon. As a participant in the collection of the data, I know, Dr. Hickok, that you have done a tremendous amount of work. Your presentation indicates that you have given this matter a great deal of thought. In answering Dr. Laros' comment about training and experience, please explain how would you advise an obstetrician who would like to perform percutaneous umbilical blood sampling for the first time. How should this person prepare for a procedure that, as noted by Dr. Parer, carries a substantial risk?

DR. DUNCAN NEILSON, Portland, Oregon. My question relates to the long term follow-up of the fetus. In the fetus the foramen ovale is open, creating the possibility of embolization to the brain from procedures done on the peripheral circulation. Injuries from that source may not become apparent until some months downstream. In your study or in other large scale collaborative studies do you look for subtle injury of that type at follow-up?

DR. LOUIS A. VONTVER, Seattle, Washington. I am puzzled by the use of this test for idiopathic thrombocytopenic purpura. If the baby has a coagulation disorder, percutaneous umbilical blood sampling is a much more dangerous test. If the baby doesn't have it, the test doesn't need to be done. Why recommend per-

cutaneous umbilical blood sampling for this purpose? Do you feel that there is no increased danger?

Dr. Hickok (Closing). Dr. Laros, it is with trepidation that I begin this discussion with you seated there. It recalls a scene 18 years ago when I was a third-year medical student and you were the junior faculty member. It is true that there were only six institutions of the 13 that collected all of the information that we needed. For the others, the data was incomplete or missing. I don't have exact information about how many operators performed percutaneous umbilical blood sampling at each center, but it was generally two or three.

The use of percutaneous umbilical blood sampling allows us to obtain a fetal karyotype quickly in situations where a fetal anomaly is discovered at an advanced gestational age. The karyotype from cultured peripheral leukocytes in the fetal circulation can be obtained in 48 hours. With amniocentesis and culture of amniocytes, it takes 7 to 14 days. Because of the increased chance of an abnormal karyotype in the fetus with a neural tube defect, parents were offered a choice of this potentially more risky procedure to have the benefits of a rapid karyotype.

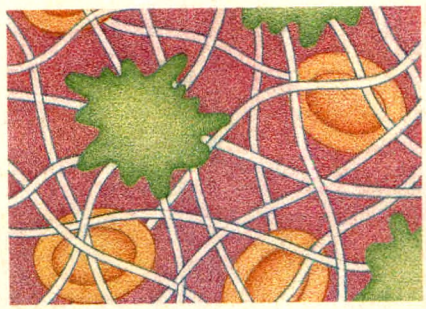
Both you and Dr. Vontver asked why this approach was used in patients with idiopathic thrombocytopenic purpura. I have not looked in detail for what information was obtained in these 20 cases and how it was used. Perhaps I will join into that argument next year at this meeting.

Finally, you and others asked how many percutaneous umbilical blood sampling procedures per year per operator are required to maintain proficiency? It is not easy to answer this very important question. By and large the same operators that do percutaneous umbilical blood sampling do multiple other ultrasonographically guided procedures requiring hand-eye coordination, amniocentesis, chorionic villus sampling, and fetal tissue biopsy. It is difficult to separate percutaneous umbilical blood sampling from these other diagnostic procedures done by perinatologists in terms of the training required to attain proficiency or the amount of practice needed to maintain proficiency.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

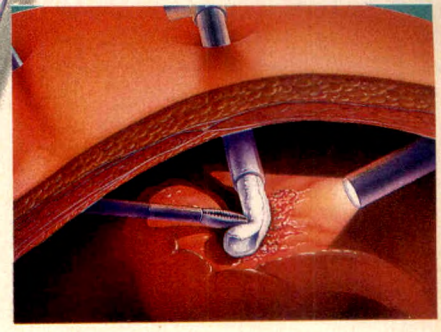


NEW from MedChem Products

Endo-Avitene™
Microfibrillar Collagen Hemostat in an Endoscopic Delivery System.

Avitene® Microfibrillar Collagen Hemostat (MCH) is now packaged ready for use in a unique delivery system designed for endoscopic procedures. This 100% collagen topical hemostat:

- eliminates risk of thermal damage.
- adheres tenaciously to the bleeding site.
- allows for the easy removal of excess by irrigation and suction.
- is effective in controlling delayed bleeding.
- is absorbable.



The Endo-Avitene device makes delivery and application of Avitene MCH to the bleeding site easy. Simply insert the delivery system through a 10 mm trocar sheath and deliver Avitene MCH directly to the bleeding site. Avitene MCH is positioned using a unique blunt plunger tip that can be used to apply pressure during placement.

MCH potentiates the clotting mechanism by attracting platelets.

We control bleeding. We reduce risk. And we deliver.

Contact us to arrange a demonstration. We'll supply the Endo-Avitene device free of charge. Call us today, and we'll deliver: 1-800-451-4716 (in Massachusetts, 617- 938-9328).

Endo-Avitene, for use in endoscopic procedures.

FIRST INTERNATIONAL MEETING ON PRACTICAL OBSTETRICS

MAIEUTICA

UNDER THE AUSPICES OF THE
INTERNATIONAL FEDERATION OF GYNAECOLOGY & OBSTETRICS

FIGO

PARIS, FRANCE **MAY 25-28, 1993**

MAIEUTICA, the First International Congress on Practical Obstetrics sponsored by the International Federation of Gynaecology and Obstetrics (FIGO) and supervised by renowned members of the Advisory Board, is devoted to practitioners. All communications are intended to help them in their therapeutic decision-making and in patient management. There will be three days focusing on major obstetrical issues such as hypertension, diabetes, uterine scarring, and multiple pregnancy, and one day set aside for shorter papers on topical subjects.

Pr. Claude SUREAU
FIGO President (1982-1985)

Main Topics of the Conference

Diabetes & Pregnancy

* Fetal malformations in diabetic pregnancies: prevention
* Treatment of diabetes during pregnancy
* Treatment of diabetes during labour
* Detection of gestational diabetes
* Management of gestational diabetes
* Fetal & neonatal complications in diabetes management

Hypertension in pregnancy

* Predicting development and prevention of preeclampsia
* Termination of pregnancy in hypertensive disorders: arguments of decision
* Management of severe preeclampsia
* Management of eclampsia
* Complications of eclampsia
* Evaluation of uterine and fetal-placental circulation by doppler ultrasound
* Liver and preeclampsia
* Pathogenesis of preeclampsia

Multiple Pregnancy

* Death of a single twin in Utero
* Twin transfusion syndrome: diagnosis, complications and management
* Differed delivery in multiple pregnancy
* Selective abortion in multiple pregnancy

Prior caesarean section and labour

* Vaginal delivery after caesarean section
* Uterine rupture during labour: diagnosis & management

New developments in obstetrics (non exhaustive)

* Different aspects of amniotic fluid embolism
* Maternal and fetal death
* Indications of cervical cerclage
* Prevention of premature labour
* Management of spontaneous repeated abortions
* Viral diseases and pregnancy
* Management of prolonged pregnacies
* Prevention and management of should dystocia

Contraception PLUS reversibility for the woman planning her childbearing years

Because she needs an effective contraceptive that she can stop when she wants, and go back to when she wants.*

TRI-LEVLEN®

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

ENHANCING YOUR PERCEPTION OF ORAL CONTRACEPTION

*Serious as well as minor side effects have been reported with the use of all oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

BERLEX Dedicated to innovation in OB/GYN medicine

914300075

TRI·LEVLEN® Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen

TRI-LEVLEN® 28 TRI-LEVLEN® 21

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use this product as a method of contraception.

Contraindications

Oral contraceptives should not be used in women with any of the following conditions: thrombophlebitis or thromboembolic disorders, a past history of deep-vein thrombophlebitis or thromboembolic disorders, cerebral-vascular or coronary-artery disease, known or suspected carcinoma of the breast, carcinoma of the endometrium or other known or suspected estrogen-dependant neoplasia, undiagnosed abnormal genital bleeding, cholestatic jaundice of pregnancy or jaundice with prior pill use, hepatic adenomas or carcinomas, known or suspected pregnancy.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, gallbladder disease, and hypertension, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long-term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of disease, namely, a ratio of the incidence of a disease among oral-contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the difference in the incidence of disease between oral-contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of adisease in the population. For further information, the reader is referred to a text on epidemiological methods.

1. *Thromboembolic Disorders and Other Vascular Problems*

a. *Myocardial Infarction.* An increased risk of myocardial infarction has been attributed to oral-contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral-contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral-contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in "Warnings"). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. *Thromboembolism.* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to nonusers to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep-vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped. A two-to four-fold increase in relative risk of postoperative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate post partum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four to six weeks after delivery in women who elect not to breast-feed, or a midtrimester pregnancy termination.

c. *Cerebrovascular diseases.* Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and nonusers, for both types of strokes, while smoking interacted to increase the risk for hemorrhagic strokes. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women.

d. *Dose-related risk of vascular disease from oral contraceptives.* A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high-density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high-density lipoprateins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogen used in the contraceptive. The amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral-contraceptive agents should be started on preparations containing less than 50 mcg of estrogen.

e. *Persistence of risk of vascular disease.* There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral-contraceptive formulations containing 50 micrograms or higher of estrogens.

2. *Estimates of Mortality from Contraceptive Use.* One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral-contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral-contraceptive users is based on data gathered in the 1970's–but not reported until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral-contraceptive use to women who do not have the various risk factors listed in this labeling. Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with oral-contraceptive use after age 40 in healthy nonsmoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception. Therefore, the Committee recommended that the benefits of oral-contraceptive use by healthy nonsmoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. *Carcinoma of the Reproductive Organs.* Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The overwhelming evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and nonusers and differences in age at start of use, has been questioned. Some studies suggest that oral-contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral-contraceptive use and breast and cervical cancers, a cause-and-effect relationship has not been established.

4. *Hepatic Neoplasia.* Benign hepatic adenomas are associated with oral-contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral-contraceptive users. However, these cancers are extremely rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral-contraceptive users approaches less than one per million users.

5. *Ocular Lesions.* There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. *Oral-Contraceptive Use Before or During Early Pregnancy.* Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. Studies also do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb-reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing oral-contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral-contraceptive use should be discontinued if pregnancy is confirmed.

7. *Gallbladder Disease.* Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral-contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral-contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. *Carbohydrate and Lipid Metabolic Effects.* Oral contraceptives have been shown to cause glucose intolerance in a significant percentage of users. Oral contraceptives containing greater than 75 micrograms of estrogens cause hyperinsulinism, while lower doses of estrogen cause less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the nondiabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see "Warnings" 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral-contraceptive users.

9. *Elevated Blood Pressure.* An increase in blood pressure has been reported in women taking oral contraceptives and this increase is more likely in older oral-contraceptive users and with continued use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing quantities of progestogens. Women with a history of hypertension or hypertension-related diseases, or renal disease should be encouraged to use another method of contraception. If women with hypertension elect to use oral contraceptives, they should be monitored closely, and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension among ever-and never-users.

10. *Headache.* The onset or exacerbation of migraine or development of headache with a new pattern that is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. *Bleeding Irregularities.* Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. The type and dose of progestogen may be important. Nonhormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent.

Precautions

1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. (See "Warnings" 1d.) 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine-and liver-function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral-contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See "Warnings" section. 10. PREGNANCY. Pregnancy Category X. See "Contraindications" and "Warnings" sections. 11. NURSING MOTHERS. Small amounts of oral-contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

Information for the Patient

See Patient Labeling.

Adverse Reactions

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see "Warnings" section): thrombophlebitis, arterial thromboembolism, pulmonary embolism, myocardial infarction, cerebral hemorrhage, cerebral thrombosis, hypertension, gallbladder disease, hepatic adenomas or benign liver tumors.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: mesenteric thrombosis, retinal thrombosis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: nausea; vomiting; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; temporary infertility after discontinuation of treatment; edema; melasma which may persist; breast changes: tenderness, enlargement, secretion; change in weight (increase or decrease); change in cervical erosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: congenital anomalies, premenstrual syndrome, cataracts, optic neuritis, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, cerebral-vascular disease with mitral valve prolapse, lupus-like syndromes, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function, hemolytic uremic syndrome, Budd-Chiari syndrome, acne, changes in libido, colitis, sickle-cell disease.

Overdosage

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits

The following noncontraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral-contraceptive formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: increased menstrual cycle regularity, decreased blood loss and decrecsed incidence of iron-deficiency anemia, decreased incidence of dysmenorrhea.

Effects related to inhibition of ovulation: decreased incidence of functional ovarian cysts, decreased incidence of ectopic pregnancies.

Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence of acute pelvic inflammatory disease, decreased incidence of endometrial cancer, decreased incidence of ovarian cancer.

Dosage and Administration

To achieve maximum contraceptive effectiveness, TRI-LEVLEN® tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours.

For full details on dosage and administration see prescribing information in package insert. 60627-0 5/90

Hysteroscopic myometrial biopsy: Its use in diagnosing adenomyosis and its clinical application

Arthur M. McCausland, MD
Sacramento, California

OBJECTIVE: The purpose of this study was to develop and clinically evaluate a hysteroscopic myometrial biopsy for diagnosing adenomyosis.
STUDY DESIGN: Ninety patients with menorrhagia had myometrial biopsies. The depth of adenomyosis was correlated with the severity of menorrhagia.
RESULTS: Of the 90 patients studied, 50 had hysteroscopically normal appearing cavities (i.e., without polyps or submucous myomas). Of those 50, 33 (66%) had significant adenomyosis (>1 mm) as compared with controls (0.8 mm). A statistically significant correlation between the depth of adenomyosis and the severity of menorrhagia was found. ($p = 0.05$).
CONCLUSION: A myometrial biopsy can diagnose adenomyosis. Minimal adenomyosis can be treated definitively by endometrial ablation. Deep adenomyosis should be treated with a hysterectomy. Endometrial glands left under a scar could not only bleed and cause pain but also have malignancy potential. The scar may delay bleeding and the diagnosis of endometrial cancer. Routine myometrial biopsy at the time of operative hysteroscopy should be added to our diagnostic armamentarium. (AM J OBSTET GYNECOL 1992;166:1619-28.)

Key words: Hysteroscopy, myometrial biopsy, adenomyosis, abnormal uterine bleeding, menorrhagia

Adenomyosis has been difficult to diagnose without the surgical pathology of a hysterectomy specimen.

In the past, attempts to diagnose adenomyosis preoperatively with hysterography,[1] magnetic resonance imaging (MRI),[2] or ultrasonography[3] have met with little enthusiasm.

With the advent of hysteroscopy the diagnosis is less elusive. Severe adenomyosis has a typical hysteroscopic appearance of cavities and trabeculations. Milder forms of adenomyosis cannot be diagnosed visually, but require tissue for microscopic examination.

Therefore a myometrial biopsy specimen obtained at the time of operative hysteroscopy was developed and evaluated.

Several questions must be addressed.

Can a single myometrial biopsy specimen be used to adequately diagnose adenomyosis and, if so, is it representative of the entire endometrial cavity?

Is a myometrial biopsy helpful in identifying the cause of menorrhagia in patients with hysteroscopically normal appearing endometrial cavities (i.e., without polyps or submucous myomas)?

Does the depth of endometrial penetration into the myometrium correlate with the degree of menorrhagia and, if so, should the current definition of adenomyosis be changed?

Can future therapy be better tailored if the depth of adenomyosis in patients with persistent menorrhagia is known? Should a hysterectomy be recommended instead of an endometrial ablation in patients with persistent menorrhagia and deep adenomyosis?

Material and methods

Ninety consecutive patients with significant menorrhagia requiring operative hysteroscopy were studied from November 1989 to June 1991.

Most patients had regular ovulatory periods confirmed by either a luteal phase endometrial biopsy showing secretory endometrium or a serum progesterone level in the ovulatory range. All patients found to have dysfunctional uterine bleeding were cycled with progesterone. They were included in the study only if this did not correct the problem. All obese patients and all patients over 40 years of age had endometrial biopsies. Three patients were excluded because their biopsies revealed atypical adenomatous hyperplasia or endometrial cancer.

Each patient received a trial regimen of nonsteroidal antiinflammatory medication before further therapy.

From the Department of Obstetrics and Gynecology, University of California at Davis Medical School, and Sutter Community Hospital and Sutter Surgery Center.
Presented at the Fifty-eighth Annual Meeting of the Pacific Coast Obstetrical and Gynecological Society, Ashland, Oregon, September 9-13, 1991.
Reprint requests: Arthur McCausland, MD, 5340 Elvas Ave., Suite 500, Sacramento, CA 95819.
6/6/37490

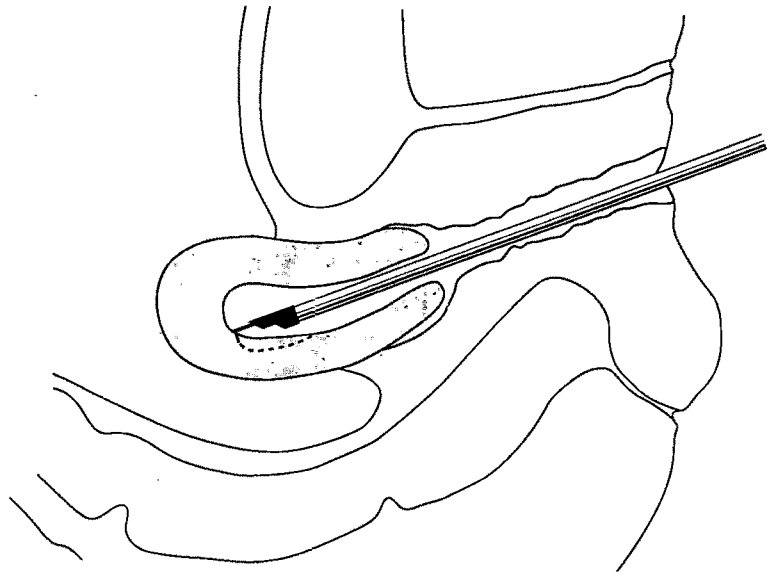

Fig. 1. Myometrial biopsy specimen being taken from the posterior uterine wall during operative hysteroscopy. A 5 mm loop electrode is used to remove a specimen 1.5 to 3 cm long.

A complete blood count and panel of thyroid tests with thyroid-stimulating hormone was included in the evaluation. Two patients were found to have elevated thyroid-stimulating hormone levels. Thyroid replacement corrected their menorrhagia.

Patients with histories of possible bleeding diathesis such as postoperative hemorrhage or easy bruising had complete coagulation work-ups. One patient was diagnosed with von Willebrand disease and had an endometrial ablation.

No office hysteroscopies were performed with this study group.

The amount of bleeding was quantified purely by clot size. Although this may be considered a gross measurement, it reflects enough bleeding to overwhelm the anticoagulant factors in the endometrium. The clot size correlated nicely with the day and night frequency of pad or tampon change in this patient population. Dime-sized clots (1.5 cm) were defined as +; quarter size (2.5 cm), + +; fifty-cent piece size (3 cm), + + +; and silver dollar (4 cm), egg or fist size + + + +. Most patients in the + + + and + + + + categories were unable to carry out their normal daily activities and had anemia.

All operative hysteroscopies were scheduled immediately after a menstrual period and were done with the patient under general anesthesia at the Sutter Surgery Center, an outpatient facility in Sacramento. A laminaria tent was inserted at least 4 hours before the surgery to facilitate cervical dilatation. After the patient was anesthetized the cervix was dilated to 31 French, and a 27 French operative hysteroscope was inserted. The endometrial cavity was thoroughly inspected with sorbitol as the distending medium, and pictures were taken.

If submucous fibroids or endometrial polyps were found they were resected with a loop electrode; a myometrial biopsy was performed followed by a curettage. If only a normal endometrial cavity was visualized, a myometrial biopsy specimen was taken followed by a thorough endometrial curettage. The hysteroscope was reinserted to ensure that all tissue had been removed.

The myometrial biopsy specimen was taken with the 5 mm loop electrode from the posterior wall (Fig. 1). With 70 W of cutting current, the loop was completely embedded 5 mm deep into the posterior myometrial wall near the fundus and a 1.5 to 3 cm segment was resected. The biopsy specimen was tapered up at the end to facilitate visualization of any bleeding sites. Bleeding was controlled with coagulating current through the loop. The biopsied tissue would usually float freely in the endometrial cavity and could easily be grasped with the loop and retracted up against the hysteroscope for removal.

Both posterior and anterior wall myometrial biopsies were performed on 15 patients to correlate the pathologic findings.

Two pathologists, Drs. Anthony Mathios and John Abele, developed a routine for processing the myometrial biopsy specimen and measuring the depth of endometrial penetration.

The specimen, which usually measures 1.5 to 3 cm in length, 5 mm in width, and 5 mm in depth, was completely fixed. The endometrial surface was the flat portion of the specimen, and the myometrial surface was the rounded or convex portion that often showed

variable blackish coagulation markings from the cautery.

The myometrial surface was inked with one of the standard marking dyes, and the specimen was longitudinally sectioned into paired halves by a single cut taken perpendicular to the endometrial surface.

The accuracy of adenomyosis measurements requires proper orientation. The surface to be cut is identified by placing that surface face down on a small orienting sponge within the processing cassette.

With a microscope fitted with a micrometer, the distance between the base of the deepest penetrating gland and the endometrial-myometrial junction is measured. This distance is recorded and mentioned in the final diagnosis.

Thirty consecutive hysterectomy specimens obtained at Sutter Memorial Hospital during the same time period were studied and used as controls. They were matched with the study group by age, gravida, and parity. These patients had histories of normal periods and were having surgery for prolapse, pain, endometriosis, fibroids, or cervical or ovarian tumors. The clot size, if any, could not be determined because this was a chart review. For consistency Dr. Mathios did all measurements for the study group and controls.

Nonparametric statistical analysis was performed.

Results

Ninety consecutive patients with menorrhagia had myometrial biopsies performed at the time of operative hysteroscopy. Of these, 50 had normal-appearing cavities, 27 had gross endometrial polyps, and 13 had submucous myomas.

Table I lists the 50 patients with normal-appearing endometrial cavities. The group is organized by depth of endometrial penetration into the myometrium, with the deepest listed first. Each patient's age, gravida, parity, and amount of menorrhagia are included. There is a good correlation between the amount of menorrhagia (clot size) and the depth of endometrial penetration. This penetration ranged from 6 to 0 mm. The mean depth in patients with + bleeding was 0.84, + + 1.44 mm, + + + 2.98 mm, and + + + + 2.35 mm.

Nonparametric statistical tests showed that a woman with a grossly normal endometrial cavity who passed clots the size of a quarter or larger is 2.9 times as likely to have meaningful adenomyosis (more than 1 mm endometrial penetration) than a woman who has not passed such large clots. This difference is highly significant. The clot size does not correlate with the depth of adenomyosis in women with polyps or myomas seen at hysteroscopy.

Table II lists the control group with normal periods whose members were matched by age, gravida, and parity with the study group. This control group is organized by depth of endometrial penetration. The depth of endometrial penetration in the anterior and posterior wall has been separately listed along with the uterine weight. The depth of penetration ranged from 1.5 mm to 0 mm. The average depth of penetration in the posterior wall (mean 0.8 mm) was almost always greater than that in the anterior wall (mean 0.46 mm). The group of women with heavy menstrual periods had significantly greater posterior wall depth than women with normal periods. The average posterior wall penetration in the women with menorrhagia was nearly twice the average depth among women with normal menstrual periods. There appeared to be a shift toward extremely heavy periods (+ + + and + + + + +) when 1 mm penetration had occurred in the study group. Because the mean endometrial penetration of the posterior wall in the control group was 0.8 mm, 1 mm was selected as the depth that could potentially cause menorrhagia and was defined as significant adenomyosis.

Table III lists the 27 patients who had gross endometrial polyps. After the polyps were resected a myometrial biopsy was performed to measure the amount of endometrial penetration in these patients. Fourteen (52%) had significant penetration; however, this could not be correlated with the amount of bleeding, suggesting that the polyps are the main cause of the menorrhagia.

Table IV lists the 13 patients who had submucous myomas. After the myomas were resected, a myometrial biopsy was performed to measure the amount of endometrial penetration. Eight (61%) had significant penetration but, like the polyp group, this could not be correlated with the amount of bleeding, suggesting that the submucous myomas are the main cause of the menorrhagia. The heaviest bleeding with the largest clots and frequent anemia was in the fibroid groups.

Comment

Can a myometrial biopsy diagnose adenomyosis? This study confirms that the diagnosis of adenomyosis with endometrial penetration ≤6 mm in depth can be made with a myometrial biopsy.

Is a single posterior myometrial biopsy representative of the entire endometrial cavity? This question must be answered for this study to have validity. When diffuse adenomyosis is present, the posterior uterine wall is the area most frequently and severely affected, a fact that has been known for years and was confirmed recently with newer imaging techniques.

In 1896 von Recklinghausen[4] observed that the glandular elements in adenomyosis were more commonly found in the posterior wall of the uterus. This has been confirmed by Benson and Sneeden,[5] who found adenomyosis to be a diffuse process most frequently in the posterior wall, less frequently in the anterior wall, and rarely involving only the cornu or portions of the uterus

*Depth (mm) of endometrial penetration into the myometrium.

near the internal os. Emge[6] found endometrial invading the posterior wall more commonly than the anterior or lateral wall. Novak and Woodruff[7] reported that adenomyosis is mainly a diffuse process; as a rule the posterior wall is more severely involved. Azziz[8] states that the posterior wall of the uterus is usually involved to a greater degree by the adenomyotic process and is consequently thicker in these uteri.

The newer imaging techniques have confirmed the above findings. Bohlman et al.[3] with ultrasonography and Togashi[2] with MRI each studied adenomyosis and found it to be diffuse, with the posterior wall most severely affected.

In my study hysteroscopic anterior and posterior myometrial biopsies were performed on 15 patients. Thirty patients in the control group also had the depth of endometrial penetration measured in both the anterior and posterior uterine walls, the areas routinely sampled (Table II). In both groups adenomyosis was found to be diffuse and to involve the entire uterine

*Depth of endometrial penetration into the myometrium in the anterior and posterior uterine walls. Anterior wall mean = 0.46 mm; posterior wall mean = 0.8 mm.

cavity. Both the anterior and posterior walls were affected, but the deepest penetration was almost always in the posterior wall.

Therefore a *single* myometrial biopsy of the posterior uterine wall is not only diagnostic of adenomyosis but also represents the area most severely involved (with the deepest endometrial penetration into the myometrium).

Can a myometrial biopsy be helpful in evaluating menorrhagia when a normal cavity is visualized hysteroscopically? It is perplexing to find a hysteroscopically normal-appearing intrauterine cavity in patients with significant menorrhagia. Unfortunately, this is a common scenario.

Of the 90 patients evaluated for menorrhagia, 50 had essentially normal-appearing cavities without gross polyps or submucous myomas (Table I). Although many had abundant tissue in spite of being postmenstrual, the term "hyperplasia" was not used because it is hysteroscopically difficult to make this diagnosis. Instead, in this study these cases were placed in the normal-cavity category. Twenty-seven cases were found to have gross polyps (Table III), and 13 had submucous myomas (Table IV).

Other investigations in which hysteroscopy was used to study menorrhagia have described a similar experience (Table V).

Fraser[9] found that 94 (51%) of the 182 patients with menorrhagia had grossly normal-appearing cavities hysteroscopically. Sixteen (9%) had submucous myomas, and 29 (16%) had polyps.

Loffer[10] studied 187 patients with abnormal uterine bleeding. Of the 102 having pure menorrhagia, 68 (66%) had normal cavities. Thirteen (13%) had polyps, and 16 (16%) had fibroids.

In evaluating menorrhagia in a patient with a normal-appearing endometrial cavity, a myometrial biopsy appears to be helpful.

*Depth of endometrial penetration into the myometrium.

In my study 33 of 50 (66%) patients with normal cavities had significant adenomyosis (endometrial penetration >1 mm) as compared with controls (0.8 mm), which accounts for their menorrhagia. If heavy bleeding persists after a thorough curettage, the diagnosis of adenomyosis can explain the problem.

Of the 27 patients with gross polyps and the 13 with submucous myomas, 14 (51%) and 8 (29%) also had significant adenomyosis. If these patients continue to bleed abnormally after their polyps or myomas are successfully resected, adenomyosis may explain the problem.

Does menorrhagia correlate with the depth of endometrial penetration into the myometrium? In this study there was a statistically significant correlation between the amount of menorrhagia (clot size) and the depth of endometrial penetration when the uterine cavity appeared normal hysteroscopically.

A review of the world literature reveals only one publication addressing the possibilities that minimal endometrial penetration can cause abnormal bleeding.

Bird et al.[11] (1972) coined the term "adenomyosis subbasalis" and defined it as adenomyosis within one low power field (2 mm) below the "basal" endometrium but with no further penetration. Of the 47 patients with this and no other pathologic condition (i.e., polyps or fibroids), 28 (60%) had significant menorrhagia. Bird et al. concluded that adenomyosis subbasalis is an im-

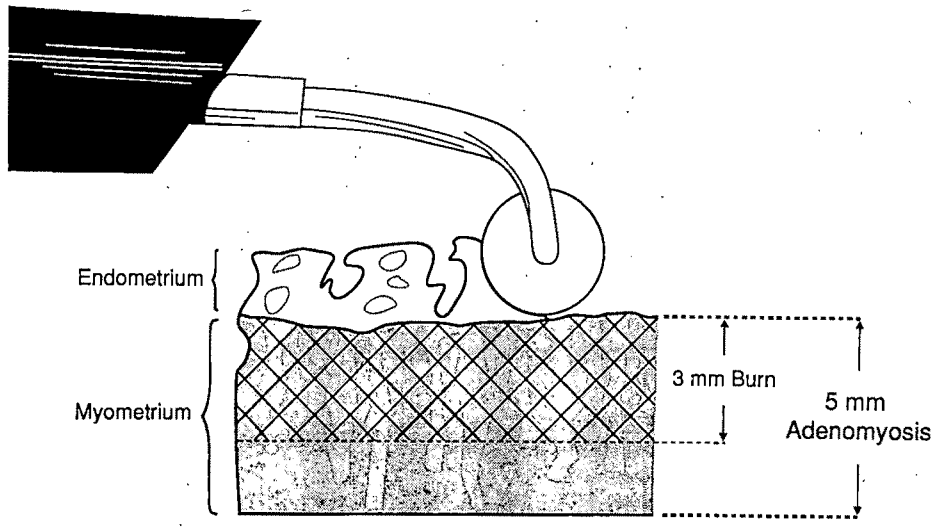

Fig. 2. Three-millimeter burn by roller-ball ablation potentially leaving endometrial glands under the scar in a patient with 5 mm deep adenomyosis.

portant symptom-producing entity and that the depth of penetration correlated with the occurrence of menorrhagia.

In an unpublished report (personal communication) Richard H. Oi, a board-certified anatomic pathologist and obstetrician-gynecologist, studied the endometrial myometrial junction in 67 patients who had had hysterectomies for prolapse, stress incontinence, and pelvic relaxation with no other uterine pathologic condition. He found an "exaggerated down growth" of endometrium into the myometrium in 31 cases, and all but four of these women had menorrhagia. Of the 36 cases with no down growth, 27 had normal periods without menorrhagia. Pathologists usually sign out these uteri as "normal." Oi demonstrated that an "exaggerated endometrial down growth" can be symptomatic.

Prognostic and future therapeutic value when adenomyosis is diagnosed by myometrial biopsy. If menorrhagia persists or recurs after a thorough curettage in a patient with a hysteroscopically normal appearing cavity or after complete resection of polyps or submucous myomas, a myometrial biopsy showing adenomyosis at the time of surgery can explain the problem.

A myometrial biopsy can demonstrate the depth of endometrial penetration, which may have prognostic value and allow the physician to tailor future therapy.

Persistent menorrhagia caused by adenomyosis in women who desire no more children can be definitively treated by either an endometrial ablation or a hysterectomy. Minimal endometrial penetration can be treated successfully with an ablation. However, it may be more prudent to treat deep adenomyosis with a hysterectomy. Endometrial glands left under a scar may cause recurrent bleeding and pain (Fig. 2). Townsend (personal communication) has performed approximately 10 hysterectomies for bleeding or pain after an endometrial ablation, and almost all have had deep adenomyosis.

Table V. Hysteroscopic findings in patients with menorrhagia

Polyps	29	16	13	13	27	30
Submucous myoma	16	9	16	16	13	15

The other long-term concern of leaving an endometrial gland under a scar is that if the ectopic gland becomes malignant, the scar could delay bleeding and the diagnosis of endometrial cancer.

This is not just a theoretical concern. Novak and Woodruff[7] state that atypical hyperplasia is not uncommonly seen in deep islands of ectopic endometrium. They reviewed the world literature of cases in which endometrial adenocarcinoma originated in the aberrant glands. They feel that this problem may be more common than reported because malignant adenomyosis may creep up to the endometrial surface and the pathologist may understandably diagnose it as endometrial carcinoma with myometrial extension.

Woodruff et al.[13] reported two cases of adenocarcinoma arising in adenomyosis diagnosed by atypical vaginal cytology. Unfortunately, postablation scarring could also prevent this diagnostic tool.

Complications of myometrial biopsies. There were no immediate or long-term complications of myometrial biopsies. Bleeding from the biopsy site can be bothersome, but coagulating the bleeder with the loop or rollerball electrode is usually successful. In one case it was necessary to inject vasopressin paracervically. No perforations occurred and are unlikely if proper technique is followed. A premenopausal uterine wall is between 1.5 and 2 cm (15 to 20 mm) thick. The loop electrode used for the biopsy is only 5 mm deep. Although hysteroscopic magnification makes it appear deeper, only one quarter to one third of the wall is being biopsied.

A myometrial biopsy should not be performed on a postmenopausal uterus, which may have a thin wall. It adds little in the evaluation of postmenopausal bleeding because adenomyosis is usually not a factor.

Ten hysterectomies have been performed for persistent menorrhagia 3 to 9 months after myometrial biopsy. There were no uterine wall defects seen at the biopsy site and no intrauterine adhesion.

In conclusion, a myometrial biopsy specimen can be used to diagnose adenomyosis. If taken from the posterior wall, it represents not only the entire endometrial cavity but also the area most severely involved.

The depth of endometrial penetration correlated closely with the degree of menorrhagia when the uterine cavity appeared normal hysteroscopically (i.e., without gross polyps or submucous fibroids).

A myometrial biopsy to determine endometrial adenomyosis has clinical significance. First, it helps the clinician make a more accurate diagnosis when evaluating menorrhagia, especially in patients with hysteroscopically normal-appearing intrauterine cavities. If a thorough curettage fails to correct the menorrhagia, a myometrial biopsy showing adenomyosis at the time of the surgery clarifies the issue.

Second, if menorrhagia persists after complete hysteroscopic resection of endometrial polyps or submucous fibroids, a myometrial biopsy showing adenomyosis can also explain this dilemma.

Third, a myometrial biopsy can demonstrate the depth of penetration that correlates closely with the amount of menorrhagia and allows the physician to tailor future therapy. If menorrhagia persists, minimal penetration may be treated definitively by an endometrial ablation. However, it may be more prudent to treat deep adenomyosis with a hysterectomy. Endometrial glands left under a scar could not only bleed and cause pain but also have future malignancy potential. The scar may delay bleeding and the subsequent diagnosis of endometrial cancer.

Routine myometrial biopsy at the time of operative hysteroscopy should be added to our diagnostic armamentarium.

I thank Drs. John Abele, Dan Egerter, Gary Fields, Charlie Gamble, France Holmes, Anthony Mathios, Richard Oi, Steven Samuel, and Duane Townsend for their valuable assistance. I also thank Vance McCausland for his technical help in preparing this paper.

Discussion

DR. WILLIAM K. GRAVES, San Francisco, California. I am pleased to discuss this paper because of my longstanding interest in this entity. I was the formal discussant for Dr. John Molitor's presentation of the subject before this society in 1970.[1]

Today Dr. McCausland presented 90 patients with significant menorrhagia in whom dilatation and curettage was indicated. Anovulatory bleeding was excluded or had failed to respond to cyclic progesterone therapy. Thyroid and hematologic disorders were ruled out by appropriate tests. Adenomatous hyperplasia and endometrial cancer had been excluded by endometrial biopsy in all patients >40 years old or who were obese. Most subjects had received a trial regimen of prostaglandin synthetase inhibitors. At the time of the dilatation and curettage, hysteroscopy was performed; this is a combination that we increasingly recognize as ap-

propriate. During the hysteroscopy Dr. McCausland took a myometrial biopsy specimen of the posterior uterine wall with a 5 mm loop electrode. This area has been recognized since the initial descriptions of adenomyosis as being most frequently involved by adenomyosis.

The great value of this study is that it includes only cases with menorrhagia. Whether the incidence of adenomyosis in women in the 40- to 50-year age range is as low as 6% or as high as 60%,[2] it is clear that it is not the presence of endometrial glands in the myometrium per se that is clinically meaningful, it is the associated symptoms. In his retrospective study of hysterectomy cases,[1] Dr. Molitor judged that in 40% of the cases adenomyosis was the primary cause of the patient's symptoms and that it was a contributing cause in another 30%. In the remaining 30%, adenomyosis was an incidental finding.

The first of my two questions is, what is the effectiveness of myometrial sampling as a diagnostic method compared with sonography, hysteroscopy alone, and MRI?

Irregular translucent myometrial zones seen on ultrasonography had been reported as being characteristic of adenomyosis. However, other reports attest to the difficulty of sonographic diagnosis of adenomyosis. For example, a retrospective report of 80 patients who had sonography before hysterectomy showed the sensitivity of sonography in distinguishing adenomyosis from leiomyomas to be 63% and the specificity to be 97%.[3] It seems to me unlikely that the vaginal probe will add much precision to this determination.

Because endometrium overlying an area of adenomyosis is often normal, making the diagnosis by hysteroscopy alone would also seem to be a hit-or-miss proposition. Dr. McCausland's data support this conclusion because 50 of his menorrhagia patients had grossly normal cavities at hysteroscopy, but two thirds of them had endometrial penetration >1 mm.

Reports of the effectiveness of MRI in differentiating adenomyosis from leiomyomas are encouraging. In a retrospective study of 93 patients with enlarged uteri,[4] MRI showed 71 had myomas, 16 had adenomyosis, and 6 had both. The MRI diagnosis was confirmed by surgery and pathologic examination in 92 of the 93 cases. In a prospective study[5] of 21 premenopausal patients with clinical diagnoses of adenomyosis, eight cases were actually adenomyosis as demonstrated by histologic findings from the hysterectomy specimen; all eight were correctly diagnosed by MRI. Another 12 had leiomyomas, 5 of which had microscopic foci of adenomyosis; 10 of the 12 were correctly diagnosed. In two cases microscopic foci of adenomyosis in myomas were not demonstrated by MRI. Although expensive, this noninvasive diagnostic method is accurate.

My second question is, to what extent is confirmation or exclusion of the diagnosis of adenomyosis necessary or even useful in management of the women with significant menorrhagia? A skeptic might say that the important considerations are the severity of bleeding and pain and the extent to which they interfere with overall health and quality of life. Only of secondary importance is whether the cause is myomata or adenomyosis. A skeptical attitude may have been reasonable 5 to 10 years ago when hysterectomy was the only treatment under consideration. However, in this age of gonadotropin-releasing hormone agonists, myomectomy, and endometrial ablation procedures, a precise diagnosis is mandatory.

Dr. McCausland expressed concern about endometrial ablation in patients with deep endometrial penetration. In an era of widespread use of hormone replacement therapy after menopause, a depth of adenomyosis >2.5 mm may be a contraindication to endometrial destruction procedures. Conversely, the absence of adenomyosis in a posterior wall biopsy supports the use of ablation if the patient so desires. It may be that myometrial biopsy should be a prerequisite for endometrial ablation when menorrhagia is the primary indication.

Dr. Joseph A. Oliver, Pasadena, California. Do you do office dilatation and curettage and hysteroscopy? Why or why not?

Dr. Lyman Rust, Hanford, California. I am glad you mentioned the problem of deep adenomyosis and the effect endometrial ablation might have in covering up endometrial tissue. It has bothered me for some time to know that there are a lot of gynecologists who rollerball patients all over the place before we know what the long-term effects are. Dr. McCausland, did you suppress these patients before hysteroscopy with danazol or a gonadotropin-releasing hormone analog? Might that affect on your biopsy results?

Dr. James A. Merrill, Seattle, Washington. It has puzzled me why adenomyosis causes menorrhagia, if indeed it does. Dr. McCausland, do you have an answer? In my experience in the pathology laboratory adenomyosis is equally often an incidental finding not occurring in a patient with symptoms of menorrhagia. Treating patients for this disorder on the basis of a biopsy diagnosis represents a considerable step forward.

Dr. Hampton W. Irwin, Spokane, Washington. Dr. Philip Brooks presented a paper last year in which he described suppression by gonadotropin-releasing hor-

mone agonist and other methods to prepare for endometrial ablation.[1] Using the same electroresection instrument that Dr. McCausland used, Dr. Brooks takes strips 4 to 5 mm in depth from most of the fundal surface and uses the rollerball for areas not adequately treated with the resectoscope. I have used that technique, and our pathologist frequently reports adenomyosis in specimens from ablations.

Dr. McCausland, your report inspires me to review my cases to find the correlation of histologic findings, history, and outcome. I expect that deeper ablation with electroresection will prove to be more effective in patients with adenomyosis than use of the rollerball alone.

DR. MCCAUSLAND (Closing). Dr. Graves, I am sure that there are cases of asymptomatic adenomyosis, but I feel that the prevalence is overstated. Almost all past studies have been retrospective chart reviews of patients found to have adenomyosis at hysterectomy. If the chart said that the menstrual periods were normal, the authors classified the case as asymptomatic. When reviewing the charts of those in the hysterectomy control group for this paper, I found how inaccurate a menstrual history from a hospital chart is likely to be. Some of these patients with "normal" periods were anemic with hemoglobin counts of 10. I called the physicians who did the hysterectomy and asked whether the periods were really normal. For example, after consulting the office record they said, "Well, they were somewhat heavy, but I was doing the surgery for stress incontinence so I just put down that the periods were okay." I question whether chart reviews for menstrual history are valid unless the author personally talked to the patient. Therefore, the incidence of "asymptomatic" adenomyosis is likely to be overstated.

Dr. Oliver, I do not think that office hysteroscopy and dilatation and curettage help much in patients with significant menorrhagia. You first need to make sure that the patient has adequate progesterone exposure by either doing an endometrial biopsy or a serum progesterone test. If in the midluteal phase the progesterone is <10 ng/ml or the endometrial biopsy specimen shows proliferative endometrium, I give the patients a 3-month course of cyclic progesterone. If this does not correct the problem I schedule an operative hysteroscopy. An office procedure at that time would be of little value for polyps or submucous myomas that need to be resected. I now feel that a patient with a grossly normal cavity needs a myometrial biopsy and a vigorous curettage. I am not talking about a wimpy suction dilatation and curettage in the office. I make sure that the endometrial lining is all out by looking afterward. If it is not, I curette again until it is. The patients who respond to this type of dilatation and curettage are those who have a normal cavity without adenomyosis. I think they have an abnormally functioning endometrium. Remember that I do these procedures immediately after the mentrual period. This is the best time to do operative hysteroscopy because at later phases there is so much build-up of endometrial tissue that finer details are obscured. Just after the menstrual period, at hysteroscopy, it is expected to see a thin lining that shows early proliferative histology. However, in most of these patients I found abundant tissue and the histology showed mixed estrogenic and progestational response, dyssynchronous endometrium, or unopposed estrogen effect. My working theory is that part of the bleeding problem in many of these patients is an abnormally functioning endometrium, perhaps some type of progesterone receptor defect.

I have not had much time for follow-up since I started this study in November 1989. However, I called my patients just before the meeting. Those with a normal cavity and <1 mm penetration by endometrium have all had normal periods since the dilatation and curettage. The ones with deeper penetration have continued to have problems, and those with the deepest penetration have had either hysterectomy or endometrial ablation. Early in this experience, I did ablations on women with deeply penetrating adenomyosis, but I found that the ones with deep adenomyosis and ablation continued to have pain or bleeding, and most have finally needed a hysterectomy.

Dr. Rust, none of these patients had hormonal suppression before the operative hysteroscopy.

Dr. Merrill, I think there are two reasons patients with adenomyosis bleed. I have already discussed the first, abnormally functioning endometrium. The other may be some type of injury to the endometrium by childbirth, endometritis, or curettage that activates the endometrium to begin penetrating into the myometrium. Of course, there is more surface area to bleed, but even more important is the fact that the endometrial penetration replaces some of the myometrial fibers. Thus the uterus does not contract effectively enough to stop bleeding.

Dr. Irwin, endometrial ablation by resection may be a good procedure for patients who have mild adenomyosis. However, technically it is hard to resect certain parts of the endometrial cavity, especially around the cornu, and you may leave some glands in that area. Using the resectoscope is definitely more dangerous than using a rollerball. There have been four deaths from uterine perforation with endometrial resections (personal communication, 1991, Duane E. Townsend, MD, Davis, California). A rollerball is easier and safer, and it should be effective, in obliterating penetration at the 1 to 2 mm range.

Neonatal morbidity according to gestational age and birth weight from five tertiary care centers in the United States, 1983 through 1986

OBJECTIVES: This study details the incidence, by gestational age and birth weight, of specific neonatal morbidities in singleton neonates without major congenital anomalies.

STUDY DESIGN: Data were prospectively collected on all deliveries at five tertiary centers in the United States during the years 1983 through 1986. Pregnancies were meticulously dated and the gestational ages of the neonates at delivery were confirmed by Dubowitz score.

RESULTS: The incidence of respiratory distress syndrome gradually decreases with increasing gestational age until 36 weeks. A marked decrease in the incidence of necrotizing enterocolitis, patent ductus arteriosus, intraventricular hemorrhage, and sepsis occurs after 32 completed weeks. The number of days of mechanical ventilation for respiratory distress syndrome and newborn stay in the tertiary care facility also were significantly reduced after 32 weeks.

CONCLUSIONS: The incidence of both respiratory distress syndrome and patent ductus arteriosus is markedly decreased by both increasing gestational age and birth weight. The incidence of grade III and IV intraventricular hemorrhage, necrotizing enterocolitis, and sepsis virtually vanishes after 34 weeks. These data relating neonatal morbidities to gestational age are important to the obstetrician in the critical decision regarding the timing of delivery and to the parents, who can benefit from a realistic prediction of the neonatal course. (AM J OBSTET GYNECOL 1992;166:1629-45.)

Key words: Neonatal morbidity, gestational age, respiratory distress syndrome, intraventricular hemorrhage, sepsis

Decisions about the timing of preterm birth are made daily in our tertiary obstetric units. It is essential that the obstetrician making these decisions has information about the incidence of specific neonatal morbidities with respect to gestational age. Balancing the consequences of a preterm delivery with its attendant neonatal morbidities against the maternal risks of continuing a complicated pregnancy is a very complex process. For instance, in the case of a mother with preterm labor the issues include whether to treat the labor, the length of treatment, the choice of single or multiple tocolytic agents, the risk of potentially life-threatening side effects of tocolytic medication on the mother,[1] and the possibility of masking a serious maternal condition (e.g., chorioamnionitis) by treating the preterm labor. The decision process is based on the principle of delivering the neonate with the least morbidity without placing the mother at excessive risk. Clearly, a key element in this decision process is an accurate prediction of a gestational age–specific neonatal morbidity.

In previous reports the incidences of neonatal morbidities are most commonly categorized according to birth weight interval.[2] If the incidence is presented by gestational age, there is usually no notation about the accuracy of prenatal dating. However, the obstetrician making the decision about the timing of a preterm birth usually has more confidence in the gestational age than in the estimated fetal weight. Even when fetal weight is estimated by ultrasonography, there can be complicating factors affecting the accuracy of the estimate, such as presence of ruptured membranes, the inherent error of the various algorithms for estimating fetal weight, inability to attain certain measurements secondary to fetal position, and the lack of sophistication

of available equipment. This paper emphasizes the incidence of selected neonatal morbidities at specific gestational ages in 20,680 carefully dated, uncomplicated pregnancies. Some of the data will also be described by birth weight, an approach that may be more useful to pediatricians, neonatologists, and hospital administrators. Selected major morbidities will also be described in categories combining birth weight and gestational age.

Methods

Maternal demographic and neonatal outcome data from five tertiary care centers in the United States were obtained from 1983 through 1986. Patients included in this analysis had a last normal menstrual period between November 1, 1982, and December 9, 1985. The data were collected in conjunction with a clinical trial of a preterm birth prevention program in high-risk mothers sponsored by the March of Dimes Birth Defects Foundation. The five centers were the University of Alabama in Birmingham (University Hospital and Cooper Green Hospital), University of California Medical Center at San Diego, Vanderbilt University (Nashville General Hospital, Vanderbilt University Hospital), Ohio State University, and Northwestern University Medical Center. The University of California Medical Center at San Francisco served as the site of data management and analysis. Virtually all pregnant women (low and high risk for preterm labor) who used these centers for their prenatal care were included. However, each center was allowed to determine certain categories of patients to be excluded from the study. Examples include private patients, patients being followed in special clinics for medical complications of pregnancies, such as diabetes, and patients entered into other protocol studies. Maternal and neonatal transports to the centers were excluded at all centers.

Patients were managed according to policies and procedures extant at each center. In general, patients with ruptured membranes did not receive tocolytic drugs. Regardless of the status of the membranes, most patients did not receive corticosteroids.

A delivery data form was completed for each patient at the time of delivery. This form was sent to the University of California Medical Center at San Francisco for data entry 30 days after delivery regardless of whether the neonate was still hospitalized. Data was entered and edited by means of a commercially available information system and a mainframe computer. Internal logistic quality control mechanisms were built into the data entry mechanisms. Any cases not passing the quality control screens resulted in the forms being sent back to the individual sites for review and resubmission. A nurse-clinician from the medical center visited each study site annually to review adherence to protocol and data abstraction. At each visit a random sample of records were reabstracted and compared with the original data.

Determination of gestational age was made meticulously. Assigned prenatal gestational age was based on date of the last menstrual period, the clinical exam at the first visit, and ultrasonography, if performed. A neonatal gestational age was assigned with a modified Dubowitz examination. Each principal investigator reviewed the gestational age assignments of neonates weighing <2750 gm. If there was <3 weeks discrepancy between the prenatal gestational age and the assigned neonatal gestational age, the prenatal gestational age was the final gestational age. If there was a discrepancy of ≥3 weeks, or ≤2 weeks spanning the thirty-seventh week, a preassigned independent obstetrician-observer not otherwise associated with the study assigned the final gestational age after review of all appropriate dating parameters.

From the population of 25,481 we created a subpopulation with the following criteria: (1) live-born, (2) singleton pregnancy, (3) inborn at tertiary care fa-

cility, (4) final gestational age between 23 and 44 weeks, (5) birth weight >500 gm, and (6) neonatal survival >24 hours. Infants who died within the first 24 hours of life were excluded, to allow a minimum time for the development and diagnosis of a specific neonatal morbidity, e.g., patent ductus arteriosus, necrotizing enterocolitis.

Gestational age was defined as completed weeks and was analyzed weekly from 23 through 36 weeks and every 2 weeks from 37 until 44 weeks. Thus an infant

delivered at 23⅘ weeks was recorded as 23 weeks of gestation. Birth weight categories were described in 100 gm intervals from 500 until 999 gm, 250 gm intervals from 1000 to 3999 gm, and ≥4000 gm.

Once the subpopulation was defined, additional maternal and neonatal exclusions were based on a maternal or neonatal condition that could affect a specific morbidity or birth weight, e.g., the increased incidence of respiratory distress syndrome (RDS) in neonates of diabetic mothers or the decreased birth weight of those neonates whose mothers have hypertension. Maternal exclusions included mothers with hypertension, preeclampsia, diabetes (classes A through R), abruptio placentae, placenta previa, renal disease, hemoglobinopathies, systemic infections, substance abuse, and collagen disease. Because population-specific growth curves were not available for each geographic region represented, intrauterine growth retardation was not an exclusion. Additionally, the population studied included 46.4% black women; some data suggest that a different population-specific growth curve be used.[3] The data were analyzed before and after the application of the maternal exclusions. Neonatal exclusions included neonates with congenital anomalies (structural or chromosomal) and congenital infections.

Standard definitions of the neonatal morbidity categories were used by the participating institutions. RDS was defined as the early onset of tachypnea, retractions, and oxygen requirement with radiographic confirmation. Infants with transient tachypnea, meconium aspiration, pulmonary edema, and pneumonia were specifically not included in the RDS category. Patent ductus arteriosus was defined as a systolic murmur accompanied by bounding peripheral pulses with either development of pulmonary edema or echocardiographic confirmation of a left-to-right shunt. Intraventricular hemorrhage was diagnosed with routine ultrasonography or computerized tomography and was classified as grade I to IV according to Papile. Infants weighing <1500 gm were routinely screened for intraventricular hemorrhage. Infants weighing ≥1500 gm had radiographic evaluations for intraventricular hemorrhage only if they were symptomatic. Necrotizing enterocolitis was diagnosed by a combination of abdominal disten-

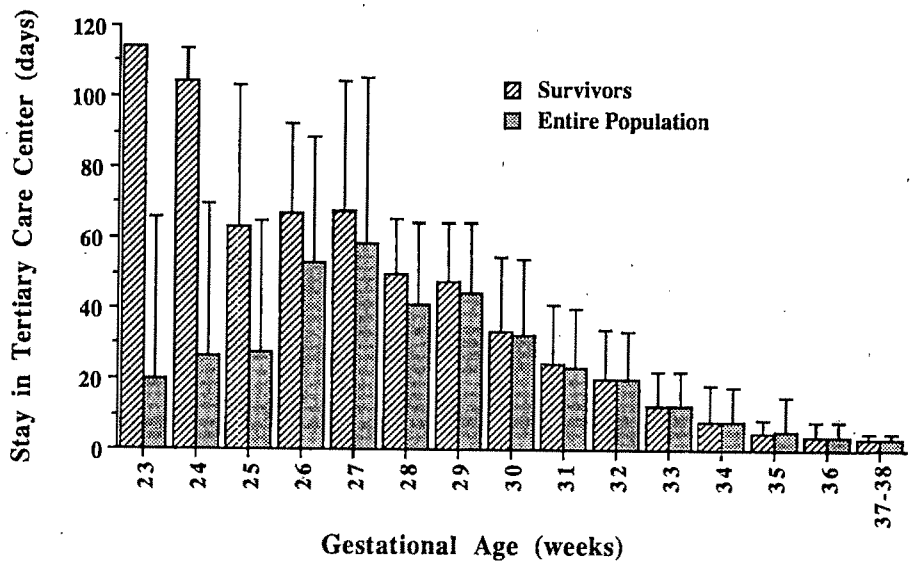

Fig. 4. Mean number of days stay at tertiary care center for total population and survivors, displayed by gestational age at birth.

tion and evidence of intramural air or perforation. Infants with hyperbilirubinemia were described in two groups: those requiring phototherapy and those requiring exchange transfusion. These therapies were initiated according to each nursery's usual protocol. Sepsis was a broad category and included early onset neonatal sepsis or meningitis and nosocomial infections of blood or spinal fluid. Infants with suspected sepsis but negative cultures were not included. Hypoglycemia was defined as blood glucose <30 mg/dl or a capillary qualitative glucose of ≤25 mg/dl.

The incidences of the above-defined neonatal morbidities were calculated by gestational age and birth weight. Similarly, the percent of neonates not having any of the selected morbidities was described. The incidence of admission to the neonatal intensive care unit

or intermediate care unit was also determined The mean number of days on mechanical ventilation for neonates ventilated for RDS and the mean number of days for newborn stay in the tertiary care facility were calculated for both survivors and the entire subpopulation. Because the number of neonates in the gestational age categories 23 and 24 weeks and birth weight categories 500 to 599 and 600 to 699 gm were so small, the incidences of neonatal morbidities in these categories are not included in the figures but are described in Appendixes I and II. For some analyses, the data were further subcategorized by sex and by ethnicity. For selected comparisons in regard to sex or ethnic group, the standard errors of incidence rates were computed to assist in evaluating the significance of observed differences with the formula:

$$\sqrt{\frac{P\,(1-P)}{N}}$$

where N is the total number of neonates and P is the incidence of event (e.g., morbidity). The best-fit fifth-order polynomial curve was plotted to depict the incidence of major neonatal morbidities. Modified birth weight–gestational age charts[4] for gestational ages 25 through 44 weeks and birth weight intervals from 700 to 4000 gm were prepared by plotting incidence rates by combined gestational age and birth weight for a more specific examination of how a birth weight cate-

Results

A total of 25,481 babies were delivered at the five centers and are recorded as part of our study population. Table I describes the various exclusions resulting in a final population of 20,680 neonates. Conditions contributing to maternal exclusions are listed in Table II. Table III describes the ethnicity of the pregnant women by center. The overall ethnic composition was 46.4% black, 35.4% white, 16.3% Hispanic, and 1.8% other. Table III also includes the total number of patients contributed by each of the seven hospitals in the five different centers. Maternal age distribution was fairly even, with ages 21 through 25 years contributing the largest number of patients to the study. Fifty percent of the patients were married. Educational level varied: 59.4% of the population had ≥12 years of education and 11.8% had ≤8 years. Sixty-eight percent of the population had seven or more prenatal visits, 15% had four to six visits, 9% had one to three visits, and 8% had no prenatal visits. Evaluation of data accuracy by reabstraction of data by the nurse-coordinator revealed an error rate of <1%. These errors were random in occurrence. Only 4.2% of the 20,680 neonates in our subpopulation had a final gestational age that required adjustment by the independent observer.

We would like to emphasize that there were differences in management protocols between the five centers with respect to the administration of corticosteroids for fetal lung maturation, the use of tocolytics, and the management of prolonged premature rupture of membranes. Of the 697 deliveries occurring from the twenty-third through the thirty-fourth week of gestation, 195 (30%) had ruptured membranes at the time of admission. Of the 502 with intact membranes, 358 (71%) received parenteral or oral tocolytic medications and 101 (20%) received corticosteroids for fetal lung maturation. Because our priority was to study the incidence of overall neonatal morbidities in uncomplicated pregnancies and to obtain the largest number of neonates per gestational age category, we did not subdivide the already small number of neonates into groups on the basis of membrane status or medications received.

Figs. 1 and 2 describe the incidence of specific neonatal morbidities from 25 weeks of gestation to term. Data from the twenty-third and twenty-fourth week were not included because the number of neonates in each category were so small (6 and 12, respectively). Fig. 1 includes data on the gestational age–specific incidence of RDS *(A)*, grade III and IV intraventricular hemorrhage *(B)*, sepsis *(C)*, and necrotizing enterocolitis *(D)*. Fig. 2 depicts similar data for patent ductus arteriosus *(A)*, hyperbilirubinemia treated with phototherapy *(B)*, and hypoglycemia *(C)*. Fig. 2, *D*, describes the gestational age–specific incidence of having neither hyperbilirubinemia treated by exchange transfusion nor one or more of the other six specific morbidities. Fig. 3 describes the mean number of days (with standard deviation) of mechanical ventilation for neonates in whom RDS developed. Data for both surviving infants and all infants ventilated are presented. In the 35-week category, there is an increase in the mean num-

ber of days ventilated at 34 weeks from 3.1 to 8.7. However, one neonate is responsible for this increase (birth weight of 750 gm at 35 weeks with 147 days on mechanical ventilation). If this one neonate was eliminated, mean number of days would become 1.0 ± 1.53 days. Fig. 4 describes the mean number of days (with standard deviation) of neonatal stay in the tertiary care facility for both all neonates and survivors.

All morbidities were also examined in subcategories of ethnicity, maternal age, and newborn sex. No statistically significant differences were found except in two subgroups. The incidence of hypoglycemia was significantly higher in Hispanic neonates weighing 4000 to 4999 gm (2.8% in Hispanic, 1.3% in white, and 1.5% in black neonates), and the incidence of neonatal hypoglycemia was higher for women over the age of 30 (0.8% <30 vs 2.1% >35). This latter finding occurred despite the exclusion of maternal diabetes.

Tables IV, V, VI, VII, VIII, and IX describe the incidence of the more frequent major neonatal morbidities (RDS, intraventricular hemorrhage, sepsis, necrotizing enterocolitis, patent ductus arteriosus, and hypoglycemia) within combined birth weight–gestational age categories.

Appendix I contains a complete tabulation on all data on the specific neonatal morbidities and the frequency

of admission to the intensive care nursery displayed by gestational age. Appendix II includes the same data displayed by birth weight category.

Comment

This study presents data from a large number of pregnant women who had prospectively dated pregnancies and whose neonates were examined for specific morbidities. Pregnancies from five centers across the United States are included. The only previous study of neonatal morbidity in well-dated pregnancies was in a very limited population of 170 neonates.[5] Maternal demographic characteristics of our population generally represent low- to middle-class women with a large representation by blacks. The majority of the pregnant women (68.7%) in this study had more than six prenatal visits. The combination of the large number of prenatal visits by the majority of women and the readjustment of only 4.2% of final gestational ages supports the accuracy of prenatal assignment of gestational age.

The incidence of RDS is probably the most frequently studied morbidity published in the literature. Our study confirms previous studies of the incidence at approximately a 55% to 65% risk at 28 to 30 weeks of gestation and 30% to 40% risk at 31 to 33 weeks of gestation. Our study also shows an extremely high incidence (80% to 90%) of RDS from 25 to 27 weeks of gestation. These incidences are similar to the smaller study by Konte et al.[5] However, one difference from that study is the increased incidence of RDS at 35 (6.4%) and 36 weeks of gestation (3.3%). This incidence at 35 and 36 weeks could possibly be decreased by more aggressive use of amniocentesis to identify the fetus at risk and use of tocolysis and corticosteroids as indicated. A report in 1979 by Ballard et al.[6] showed a 93% incidence of RDS in infants 500 to 750 gm whose mothers did not receive antenatal steroids. This figure is slightly higher than our incidence in birth weight category of 500 to 799 gm. More recent publications compare the incidence of RDS in control versus treatment groups with various modalities including antenatal steroids, thyroid-releasing hormone, tocolytics, and prophylactic surfactant replacement.[7-9] Our data consists of infants born to mothers in tertiary centers, some of whom had prolonged ruptured membranes, antenatal steroid therapy, or tocolytic therapy and should reflect optimal management at that time. Still, the incidence of RDS in our study is extremely high at 23 to 27 weeks of gestation. Because the severity of RDS was not coded on the data entry form, the cases of severe versus moderate or mild disease could not be delineated. Our data fail to confirm a consistently decreased incidence of RDS in black neonates compared with white neonates when analyzed by gestational age or birth weight. Of note is the decrease in the incidence with increasing birth weight within each gestational age category between 27 to 32 weeks and the decrease in incidence with increasing gestational age within each birth weight category between 1500 and 3000 gm (Table IV). Surprisingly, within the various gestational age categories at 35 to 38 weeks, there is no increase in the incidence as birth weight increases. Perhaps this finding is related to the exclusion of infants of diabetic mothers from this analysis.

The mean number of days on mechanical ventilation for the entire population with RDS (Fig. 3) does not consistently decrease with advancing gestational age

until 26 weeks of gestation, reflecting the mortality of those neonates with RDS at 23 to 25 weeks. For those survivors at 23 to 25 weeks with RDS, the average number of days on the ventilator peaks at 24 weeks (74 days) and gradually decreases with increasing gestational age. It is of note that there is an increase in mechanical ventilation required for neonates at 34 weeks of gestation, reflecting the presence of RDS as a morbidity at 34 weeks of gestation.

In this report we have focused on the incidence of severe intraventricular hemorrhage (grades III and IV), which has been associated with a definite increase in long-term morbidity, developmental delay, and neurologic abnormalities. Our data on the incidence of severe bleeding are accurate up to 1500 gm. However, we may have missed some instances in larger babies who were not evaluated radiographically because they were asymptomatic. Nonetheless, the incidence of symptomatic severe bleeding drops to zero after 32 completed weeks of gestation. In Konte et al.'s[5] small study the incidence was higher in the category 28 to 33 weeks than in our findings, but their numbers were much smaller than those of our larger study ($n = 33$ vs our 104 at 30 to 31 weeks). The incidence of intracranial hemorrhage in the literature, usually by birth weight groups, has been reported as 40% at <1500 gm.[10] McGuiness and Smith[11] reported on 112 consecutive babies between 1500 and 2000 gm who were all asymptomatic but had a 13% incidence intraventricular hemorrhage. Shinnar et al.[12] reported the incidence of

various grades of intraventricular hemorrhage by gestational age in infants weighing <1800 gm. At <26 weeks of gestation, two had grade III and IV hemorrhages, whereas by 33 to 36 weeks, none had grade III or IV hemorrhages. Pooled data on infants <1500 gm from six centers reported by Allan and Philip[13] showed the incidence of any grade of intraventricular hemorrhage to be 77% at <26 weeks of gestation, 56% at 27 to 28 weeks of gestation, 37% at 29 to 30 weeks of gestation, and 7% at or beyond 33 weeks.

In general, the incidence of patent ductus arteriosus in our study is lower than the incidence previously reported in the literature. In 1972, Kitterman et al.[14] reported a dramatically increased incidence in preterm infants. In that study in 15.3% of infants weighing <1750 gm a hemodynamically significant ductus shunt developed. Heymann[15] in 1977 reported a 45% incidence in infants weighing <1750 gm with an incidence as high as 75% to 80% in infants <1250 gm. In 1989 this very high incidence in extremely low-birth-weight infants was confirmed by Cassady et al.,[16] who found an incidence of 81% in infants weighing <1000 gm and in oxygen for lung disease. Gersony et al.,[17] in the large collaborative study of indomethacin, reported an incidence of 21% in infants weighing <1750 gm. A study of the incidence of patent ductus arteriosus on the basis of gestational age was performed by Siassi et al.[18] in 1976. The risk was as follows: 17% at 28 to 30 weeks, 44% at 34 to 36 weeks, and 7.7% at 37 to 40 weeks. This high incidence at term may represent some infants with congenital heart disease. More recently, John and Todd[19] in Australia in 1984 and 1985 evaluated at babies at 24 to 26 weeks of gestation and found significant patent ductus arteriosus in only 15 of 34 or 44%. The lower incidence in his study and in our collaborative data may reflect changes in antenatal management, including the administration of betamethasone. In fact, in 1981 Clyman et al.[20] described a significant decrease in the incidence of patent ductus arteriosus after maternal betamethasone therapy in infants weighing 500 to 1500 gm. In our gestational age–birth weight data (Table VIII), the incidence of patent ductus arteriosus decreases with advancing gestational age in the same birth weight category and also decreases with increasing birth weight within the same gestational age category. This finding parallels the pattern of the combined chart on birth weight and gestational age for RDS.

The incidence of necrotizing enterocolitis is quite variable in our study but is high up to 31 weeks of gestation, when it begins to decline, becoming quite low after 34 weeks of gestation. The incidence in the literature has varied from 3% to 10% in infants weighing <1500 gm and remains at about 1% until term.[21] The gestational age–birth weight data on necrotizing enterocolitis (Table VII) did not reveal a definite pattern of decreasing incidence until 35 weeks of gestation, or of birth weight >2000 gm, when the occurrence became rare.

The incidence of neonatal sepsis in our study was very high up to 29 weeks of gestation (25%-35%) and declined by 32 weeks. It then remained stable at 1% to 5% until a further drop at 37 weeks to 0.3% to 0.5%. The incidence of neonatal sepsis in all live births has been reported as between 0.1% to 0.4% over the last decade.[22] The incidence of infections seen in neonatal intensive care units has been much higher and continues to rise with an increasing incidence of nosocomial infections in very immature neonates with prolonged and complicated hospitalizations. Recent studies in infants weighing <1500 gm have reported incidences

varying from 8% to 70%. The National Institutes of Health neonatal network collaborative intravenous immunoglobulin trial reported a 33% incidence between 500 and 750 gm, dropping to 10% for 1250 to 1500 gm neonates.[23] Our gestational age–birth weight data on sepsis (Table VI) were similar to the above chart on necrotizing enterocolitis until 35 weeks or >2000 gm when sepsis was at a baseline of 0% to 3% with no definite pattern.

The incidence of hypoglycemia in our study was definitely higher in the very immature neonates (24 to 26 weeks of gestation) and then declined as gestational age advanced. However, in the data arranged by birth weight there is an increase in hypoglycemia in infants weighing ≥4000 gm, although infants of diabetic women and diabetic pregnant women have been excluded from our study. It is noteworthy that all centers were not routinely screening for gestational diabetes in all pregnant women during the years of the data collection. Additionally, most babies were not routinely checked for hypoglycemia. Therefore it is possible that the low incidence of hypoglycemia in term, average-sized newborns possibly reflects the fact that screening did not occur. The higher values in the small and large infants may well represent an ascertainment bias. When the birth-weight category of 4000 to 4999 gm was scrutinized carefully by ethnic group, Hispanic neonates were overrepresented, with a 2.8% incidence of neonatal hypoglycemia. This finding supports previous findings that Hispanic pregnant women have a higher incidence of gestational diabetes than white or black women.[24]

Data on mean length of stay for neonates in tertiary care facilities (Fig. 4) may be of interest to administrators in considering allocation of resources. Obviously, these data are influenced by the availability and willingness of community-based nurseries to accept transfer of these neonates. The mean length of stay was 3 days for babies at least 37 weeks of gestation but increased steadily with decreasing gestational age to a peak mean stay of 58 days at 27 weeks. At <27 weeks of gestation, infants had shorter stays, presumably because of increased mortality after the first days of life. However, when parents are counseled, the table of length of stay for survivors conveys much more accurately the likely duration of hospitalization if the infant survives the early neonatal course.

Virtually all infants <33 weeks of gestation were admitted to the intermediate or intensive care nursery. At term 10% of infants were admitted. The admission rate rose to 14% at 43 to 44 weeks and reflects the increased morbidity of postterm gestation.

We were concerned by the relatively small number of infants delivered between 23 and 34 weeks of gestation and wondered about the wisdom of our maternal exclusions. We considered the effect of these exclusions by comparing the incidence of each specific morbidity in the various weight and gestational age categories for the excluded neonates (3004) and our study populations. If the exclusions had not been made, there would have been statistically significant differences in 25 of 144 birth-weight categories and 16 of 144 gestational age categories. If we added the excluded patients the effect would be to increase the incidence of the various morbidities at the lower gestational ages and birth weights and decrease it in the large and more mature neonates.

Comment

The data presented represent the largest series of accurately dated pregnancies in which the incidence of neonatal morbidities is studied by gestational age and birth weight. In general, the incidence of both RDS and patent ductus arteriosus is markedly decreased by both increasing gestational age and birth weight. The incidence of RDS is still significant at 35 to 36 weeks of gestation. The incidence of grade III and IV intraventricular hemorrhage decreases to zero after 32 completed weeks of gestation. The incidence of necrotizing enterocolitis declines after 31 weeks of gestation and is very low after 34 weeks of gestation. The incidence of neonatal sepsis decreases after 32 weeks of gestation. The incidence of neonatal hypoglycemia is increased in premature neonates and declines gradually with increasing gestational age, unless the birth weight is ≥4000 gm, when the incidence is increased at 1.9%. This information about the incidence of neonatal morbidities by gestational age should be invaluable to the obstetrician in the critical decision regarding the timing of the delivery of the fetus and to the parents who can benefit from a realistic prediction of the neonatal course.

Discussion

DR. JIMMIE WESTBERG, San Francisco, California. Dr. Laros has presented an excellent paper describing a large series of obstetric patients who had meticulous, prospective gestational dating confirmed by Dubowitz examination of the respective newborns.

Selective morbidities of the newborn were evaluated both by the accurate gestational dates and birth weights. The purpose of this evaluation was to establish incidence norms for the specific morbidities to help in the complex decision process regarding preterm birth. However, maturity-related problems and infections are not the only problems faced in making these decisions. Neonatal mortality, neurologic handicaps, and learning disabilities must also be considered. This article accomplished its goals in a limited way. It is a beginning. It is unfortunate that mortality data were not specifically identified, as clearly these data were available.

Having been involved in the California Medical Association's Neonatal Mortality Studies for California's Health Services,[1] I can appreciate the unbelievable time and effort that goes into such studies. Devising the forms, overseeing their completion, and reviewing the computer printouts requires superhuman work, particularly when seven different hospitals are involved.

I would now like to discuss portions of this study by comparing results to the California Neonatal Mortality Study for 1984.

The present study involved tertiary centers throughout the United States. In California we have fairly well-defined obstetric units called regional centers and neonatal units noted as California Children's Services, levels I, II, and III. Usually regional centers are associated with level III nurseries. Table I shows the total live births in the designated neonatal units and their respective neonatal death rates. Only 18% of total births occurred in California's tertiary centers, certainly not a representative sampling. It is interesting to note that 31% of the deaths in level III nurseries were thought to be preventative because of suboptimal care rendered by these centers.

Table II compares the racial breakdown of the two studies listing the California State mortality data and Dr. Laros' morbidity data. The disparity between the two studies is obvious. Because mortality and morbidity rates usually parallel each other, it is apparent from this table that the black neonatal mortality rate is significantly different from all other groups. The morbidity study showed no such differences. Table III, which shows data from the California mortality study,

Table I. Place of delivery by preventability, in-hospital neonatal deaths, California, 1984

California Children's Services level of delivery hospital preventability	*Frequency and percentage*	*Total live births**	*Neonatal death rate/1000 live births†*
Home	3 (1.1%)	4,825	6.0

Race of mother	*Live Births (no. and %)*	*Race-specific neonatal death rate/1000 live births*	*Proportion of Morbidity study (%)*
White	229,053 (51.2%)	4.9	35.4
Hispanic	133,023 (29.7%)	5.0	16.3
Black	38,639 (8.6%)	13.1	46.4
Other	44,216 (9.9%)	5.7	1.8
No information	2,394 (0.5%)	—	
TOTAL	447,325 (100%)	—	100% (20,680)

may provide a partial answer to this racial discrepancy. Approximately 20% of all neonatal deaths occurred in <500 gm group. If only the black neonates are considered, 29% were <500 gm and 31% were between 500 and 750 gm. Most of these infants would have been excluded from the morbidity study. This is further substantiated by the fact that the median birth weight of black deceased neonates was 585 gm.

Several other points in this article are disturbing to me. Eight percent of the included mothers had no prenatal care yet were meticulously dated. Pregnancies with preterm labor and delivery are not uncomplicated pregnancies. A 750 gm infant born at 35 weeks who is like a 27-week neonate is not compatible with meticulous dating.

In conclusion, this is an excellent beginning. However, this study covers only a small section of our obstetric delivery system, has a distorted racial mix of patients, and has too many exclusions. In the future I hope studies of neonatal mortality and morbidity will be undertaken with standardized obstetric and neonatal forms that are meticulously completed. With this information accurate mortality and morbidity rates will be ascertained for each racial group. For now, we can say to our patients, "If your baby is born after more than 23 weeks and lives more than 24 hours, we can make some projections as to morbidity, duration of hospitalization, and financial cost."

I have several questions for Dr. Laros: (1) Why were patients from the University of California, San Francisco not included? (2) What percentage of the births occur in the tertiary centers compared with their respective catchment areas? (3) How were the meticulous dating criteria applied to the pregnancies of mothers with no prenatal care? and (4) Was the 750 gm infant who was born at 35 weeks small for gestational age?

DR. ROBERT C. GOODLIN, Placerville, California. The March of Dimes spent millions of dollars and, until now, we have heard no results. In my opinion this has been a real "black eye" for academic obstetrics. As far as I know, this is the first detailed analysis of those data. If Dr. Laros' study can be done, I don't understand why we haven't heard the rest of the story. My suspicion is, of course, that there was a negative outcome.

I have two other questions that concern RDS. First, I have always believed there was an increased incidence between 33 and 35 weeks and I thought I saw a little peak on Fig. 3. Did you see it? Second, I have also thought that when RDS occurs after 34 weeks it is often a more severe disease process. Do your data support this concept?

DR. JULIAN T. PARER, San Francisco, California. I have two comments. First, I was much more comfortable with the conclusions you previously reported—that 34 weeks was the time when the cost/benefit ratio shifted so that financially it was better to deliver a baby

Table III. Race of mother by birth weight, in-hospital neonatal deaths, California, 1984

Birth weight (gm)	*Race of mother (No. and %)*

TOTAL	115 (100%)	69 (100%)	52 (100%)	26 (100%)	5 (100%)	267 (100%)

Note: Numbers are separated by percentages in each racial category. The median birth weight for deceased neonates of white mothers was 905 gm; Hispanic mothers, 1080 gm; black mothers, 585 gm; and mothers of other races, 1345 gm.

rather than keep the mother in the hospital generating a large bill.[1] I am now a little uncomfortable with that conclusion because you have clearly shown a continuum of morbidity. Where on that continuum of newborn morbidity after 34 weeks would you allow a woman to be delivered? That is, what is an acceptable degree of morbidity?

My second question regards doing amniocentesis to determine pulmonary maturity after 34 weeks, when betamethasone has not been shown to be effective. It seems to me that because the incidence of respiratory distress syndrome is going to be 5%, or certainly in the single-digit percentages, most of those amniocenteses, lecithin/sphingomyelin ratios, phosphatidylglycerol determinations, and much of the betamethasone treatment might well be largely wasted. The question can and should be studied from the standpoint both of the cost/benefit ratio and of morbidity before we accept amniocentesis as the preferred procedure at that stage.

Dr. Laros (Closing). Dr. Westberg points out very clearly a dilemma that we faced. When the data analysis for the State of California is done, birth and death certificate information is used. Although this provides a large number of patients, the data are flawed by inaccuracies in the gestational age and by the limited number of diagnoses available on the records of both mother and infant. On birth certificates and fetal death certificates there are only four boxes for diagnosis, and we all know that many neonates who have been in the intensive care nursery have many important problems. These problems simply are not included in the data set. In our study, on the other hand, we have very precise data on a limited number of patients. As expensive as collecting these data was, to go further and attempt to gather information on learning disabilities of the offspring would be prohibitively expensive.

Why was the University of California, San Francisco not a study site? Our department already had an educational program and thus would not have been an appropriate study site.

We do not know what percentage of the total population in the area was represented by the infants delivered in each of these tertiary centers. It would be interesting to know how representative our sample was.

With respect to the meticulous dating on patients with no prenatal care, this 8% of our population was dated by the Dubowitz score, the best criterion available for patients with no prenatal care.

I do not believe that we had a 750 gm infant delivered at 35 weeks in our data set. If we had one, it obviously would have been an example of marked intrauterine growth retardation.

Dr. Goodlin, for political reasons, I will not answer the question of why so few data have been made public from the March of Dimes study. In the immediate future you can expect to see a fairly large number of publications by various investigators using this data set. The involved principal investigators agreed that it was most appropriate to separate into three reports the gestational age and birth weight data, the mortality data, and the morbidity data. Dr. Westberg, our article is lengthy, with a number of tables and appendixes, and the companion articles will have similar amounts of data.

Dr. Parer, the analysis that we have previously published[1] says that at 34, 35, and 36 weeks it is most cost-effective to allow a mother to be delivered. These data say that at these gestational ages there is a very low incidence of RDS, sepsis, and hyperbilirubinemia. Patent ductus arteriosus and intraventricular hemorrhage do not occur. You inspire me to do a cost-effectiveness analysis of amniocentesis and betamethasone use during the thirty-fourth and thirty-fifth weeks.

Deoxyribonucleic acid analysis by flow cytometry of uterine leiomyosarcomas and smooth muscle tumors of uncertain malignant potential

William A. Peters III, MD, Donald R. Howard, MD, PhD, Willie A. Andersen, MD, and David C. Figge, MD

Seattle, Washington, and Charlottesville, Virginia

OBJECTIVES: The histologic distinction of uterine benign leiomyomas from leiomyosarcomas is difficult. Ploidy analysis and measurement of the proliferative rate were examined to determine if they could distinguish malignant from benign tumors and if they were independent prognostic factors.
STUDY DESIGN: Paraffin-embedded blocks were recut and prepared for flow cytometry with the technique of Hedley. Mitotic counts and tumor grading were performed on an adjacent hematoxylin and eosin–stained section. Statistical analysis was carried out with χ^2 life-table, and Cox model analysis.
RESULTS: There were 33 patients with deoxyribonucleic acid histograms that were acceptable for analysis. Fourteen tumors were diploid and 19 were aneuploid. There were no significant differences in the clinical characteristics between the patients with diploid tumors and those with aneuploid tumors. Aneuploid tumors were more likely to have cellular atypia ($p = 0.085$). There was a strong correlation between the percentage of cells in the S phase and the mitotic count ($p = 0.0001$). Increasing mitotic count, increasing S phase, presence of extrauterine disease, and postmenopausal status were all adverse prognostic factors. However, when multivariant analysis with a Cox model was used, only S phase and presence of extrauterine disease were adverse factors. Diploid tumors have a better overall survival ($p = 0.0658$) but a similiar disease-free survival. In those patients who ultimately have relapses, diploid tumors have a significantly longer interval from relapse to death ($p = 0.0045$).
CONCLUSIONS: Neither ploidy analysis nor measurement of the proliferative rate will distinguish a benign from a malignant course in an individual patient; however, ploidy is predictive of survival from time of disease progression and proliferative rate is the strongest predictor of overall survival. The time-proven reliability of mitotic count in the diagnosis of smooth muscle tumors reflects its ability to predict proliferative rate. (Am J Obstet Gynecol 1992;166:1646-54.)

Key words: Flow cytometry, proliferative rate, ploidy, uterine leiomyosarcomas

The bizarre appearance and marked atypia of many benign uterine smooth muscle tumors have made it difficult to establish absolute histologic criteria for the diagnosis of uterine leiomyosarcomas. With currently accepted definitions, tumors that are classified as malignant have a poor prognosis, with surival of 20% to 50% in many series.[1-5] To date the most reliable criterion for the diagnosis of leiomyosarcoma has been the mitotic count in the most active portion of the tumor.[1, 3, 4, 6, 7] Currently, there is no proved efficacious adjuvant therapy.

Deoxyribonucleic acid (DNA) analysis by flow cytometry has promise in establishing the diagnosis of benign versus malignant tumors and predicting the clinical course with the tumors. Identification of diploid tumors or tumors with a low proliferative rate (S phase) is of prognostic significance in other tumors, notably ovary and breast.[8-12] Uterine leiomyosarcomas with a diploid histogram have been shown to have a better prognosis than tumors with an aneuploid pattern.[13] The usefulness of flow cytometry in ovarian tumors of low malignant potential suggests a similar use in uterine smooth muscle tumors; that was the genesis for this study.

Material and methods

Archival material was obtained from four Seattle area hospitals that are members of the Puget Sound Oncology Consortium (Swedish Hospital Medical Center, University of Washington Medical Center, Virginia Mason Medical Center, and Overlake Medical Center) and from the University of Virginia Medical Center. Par-

affin-embedded blocks were recut in areas corresponding to the most aggressive-appearing portion of tumors previously identified as leiomyosarcomas or smooth muscle tumors of uncertain malignant potential. Formalin-fixed, paraffin-embedded sections of tissue were prepared for flow cytometric analysis with modifications of a previously published method.[14] Briefly, 50 μm sections were made from a prepresentative paraffin block of tumor tissue. Sections were deparaffinized, hydrated, treated with pepsin, pepstatin A, Triton X-100, and ribonuclease. Cells were then stained with propidium iodide as the DNA fluorochrome. DNA-stained nuclei were prepared and run on an Epics C flow cytometer (Coulter Electronics, Hialeah, Fla.). A total of 25,000 nuclear events were acquired on a single-parameter, 256-channel integrated fluorescence histogram.

A cell-cycle analysis software program (Multicycle, Phoenix Flow Systems, Inc., San Diego) was used to determine cell-cycle distributions of the presynthetic growth phase (G_0G_1), synthetic phase (S), and postsynthetic and mitotic growth phases (G_2M). DNA content was defined as aneuploid if two discrete G_0G_1 peaks were observed. In addition, the aneuploid G_0G_1 peak had to contain at least 10% of the 25,000 sample events and have a corresponding identifiable G_2M peak. Visual inspection of histograms was performed. Those with excess debris or insufficient resolution to distinguish two peaks were considered uninterpretable for S-phase and ploidy determination. In this study the coefficient of variation of the G_0G_1 peak of single-peak tumors was required to be <6 for the specimen to be considered interpretable for ploidy status.[8]

All tissue was reviewed by the study pathologist (D.R.H.) without knowledge of the clinical outcome. Malignancy grading was performed with a three-grade scale based on the classic grading system proposed by Broders and Hargrave.[15] Grading was determined primarily on cytomorphologic features (cell and nuclear pleomorphism) and degree of tissue differentiation.[16] Mitotic counts were performed after the method of O'Connor and Norris.[17] To determine mitotic activity, sections were scanned under low-power magnification to identify the most mitotically active areas. These areas were counted under high-power magnification (×400, area of field 0.159 mm²), and the highest number of mitoses in 10 consecutive random fields were recorded.

The classification system of Hendrickson and Kempson was used.[7] All tumors with >10 mitotic figures per 10 high-powered fields were considered leiomyosarcomas. Tumors with five to 10 mitotic figures per 10 high-powered fields were considered sarcomas if they had grade 3 of 3 cellular atypia and pleomorphism; otherwise, they were considered tumors of uncertain malignant potential. Hendrickson and Kempson also classify tumors with two to four mitotic figures per 10 high-powered fields with marked cellular atypia and pleomorphism as tumors of uncertain malignant potential. We did not have any patients with less than five mitotic figures per 10 high-powered fields for analysis.

Table I. Clinical characteristics in 33 women with leiomyosarcoma or smooth muscle tumors of uncertain malignancy potential

	Entire group	*Diploid*	*Aneuploid*
No. of patients	33	44	19
Median age (yr)	50	49	51
Race (% white)	88	86	89
Premenopausal (%)	48	57	42
Median parity	2	2	2
Extrauterine disease (stage III or IV) (%)	33	29	37

Table II. Correlation of histology and DNA analysis

	Entire group	*Diploid tumors*	*Aneuploid tumors*	*Significance*
Mean mitotic count	22.4	15.7	27.4	$p = 0.79$
Atypia (%)				
Grade 1	42.5	57.0	32.0	
Grade 2	42.5	43.0	42.0	
Grade 3	15.0	0.0	26.0	$p = 0.085$
Mean S phase (%)	12.4	9.2	14.8	$p = 0.47$

The Student t test and χ^2 were used to compare clinical characteristics and histologic features of diploid and aneuploid tumors. Proliferative rate and mitotic count were plotted and correlated with the Spearman rank coefficient. Kaplan-Meier life-table analysis was used, and differences in survival were compared with the log-rank method.[18, 19] Cox model regression was used to simultaneously compare multiple variables with survival as the dependent end point.[20]

Results

We identified 33 patients originally diagnosed as having leiomyosarcoma who had acceptable DNA histograms with a coefficient of variation for G_0G_1 of <6. Nineteen of these tumors were aneuploid and 14 were diploid. The clinical characteristics of these patients were presented in Table I. There were no significant differences in age, racial breakdown, menopausal status, parity, or presence of extrauterine disease between aneuploid and diploid tumors.

Table II presents the correlation between histologic data and DNA analysis. Aneuploid tumors were associated with a high degree of cellular atypia ($p = 0.085$). There was no correlation between ploidy status

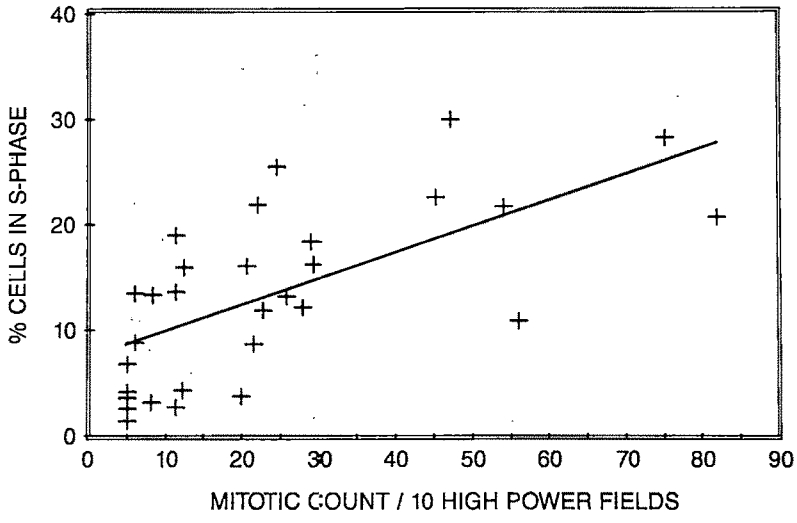

Fig. 1. Plot of S phase versus mitotic count and of linear regression of S phase predicted by mitotic count.

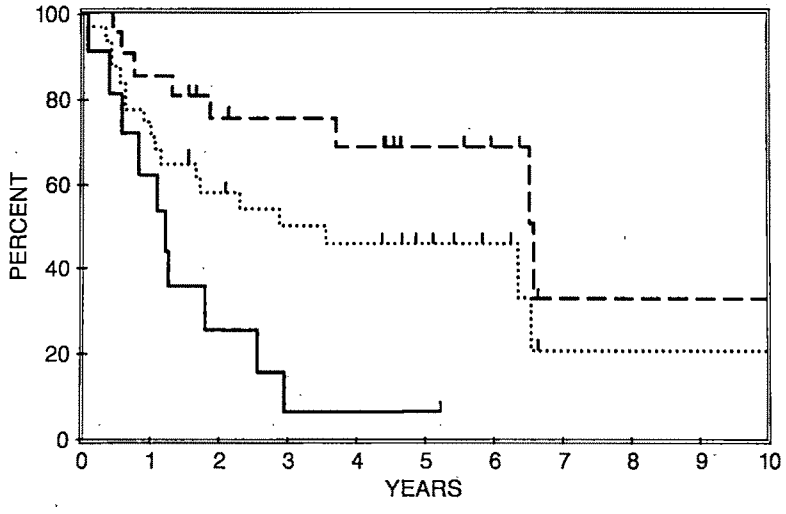

Fig. 2. Life-table survival probability for entire group and by presence or absence of extrauterine disease. *Dotted line*, All patients; *dashed line*, no extrauterine disease; *solid line*, extrauterine disease.

and mitotic count ($p = 0.79$) or between ploidy status and the percentage of cells in S phase ($p = 0.47$).

There was, however, a strong correlation between the percentage of cells in S phase and the mitotic count (Fig. 1). When S phase and mitotic count were plotted with linear regression, the mitotic count predicted 47% of the variation in S-phase measurements. The null hypothesis that there is no linear relationship is rejected at the 0.05 level ($p = 0.0001$).

Fig. 2 plots the overall survival and survival by the presence or absence of extrauterine disease. The median survival for the entire group was 43 months, with a projected 5-year survival of 49%. The presence of extrauterine disease at the time of clinical presentation was a strong clinical predictor of survival. The median survival of patients with extrauterine disease was 24 months and in patients without extrauterine disease was 79 months ($p = 0.0002$).

Fig. 3 plots survival by menopausal status. The survival advantage in premenopausal women approach statistical significance ($p = 0.0837$).

Fig. 4 presents the survival based on mitotic count. When patients are divided into three groups, there was a suggestion of a better survival with lower mitotic counts; this trend approached statistical significance when all patients with mitotic counts >10 were lumped together ($p = 0.0696$).

Fig. 5 is a plot of survival by the percentage of cells in S phase. There was a significant survival advantage for those patients with an S phase <10% ($p = 0.0221$).

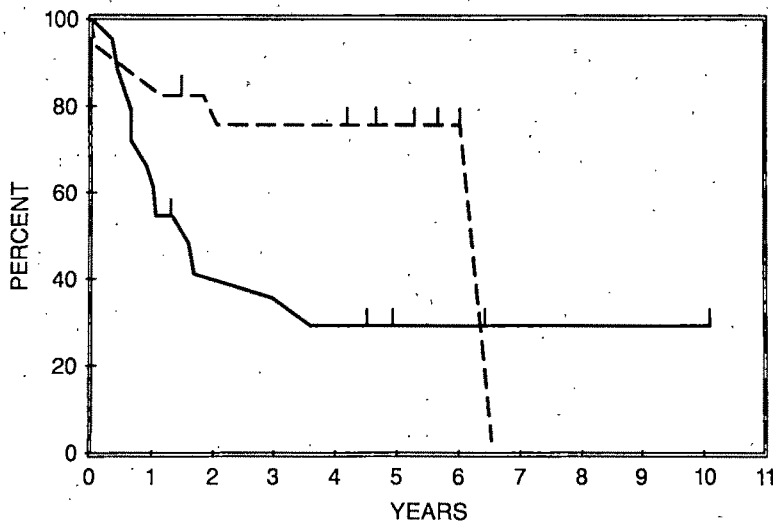

Fig. 3. Life-table survival probability by menopausal status. *Dashed line*, Premenopausal; *solid line*, postmenopausal.

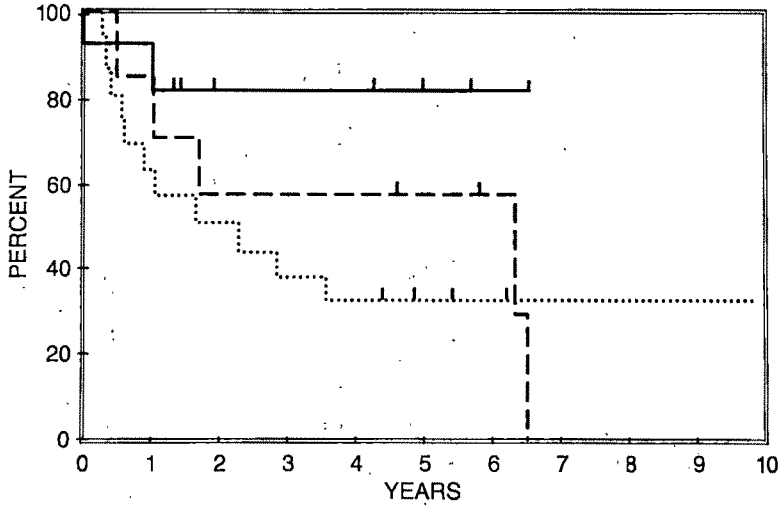

Fig. 4. Life-table survival probability by mitotic count. *Solid line*, 5 to 10; *dashed line*, 11 to 20; *dotted line*, >20.

Survival was also calculated with a break point of 12%, but in spite of moving three patients into the better prognosis group, there was almost no change in the plots ($p = 0.0271$). Because of the strong correlation between S phase and mitotic count, the two were compared in a Cox model, with survival as the dependent variable. S phase was shown to be the better independent predictor of survival (χ^2 7.95, $p = 0.0048$ vs χ^2 0.79, $p = 0.3740$).

S phase and presence or absence of extrauterine disease were compared in a separate Cox model. Both variables appeared to be independent predictors of survival (χ^2 7.21, $p = 0.0076$ for S phase; χ^2 6.73, $p = 0.0095$ for extrauterine disease). As a single variable, cellular atypia was a significant predictor of survival (χ^2 5.68, $p = 0.0200$); however, when examined in the Cox model with S phase and presence or absence of extrauterine disease, atypia was not an independent predictor of outcome (χ^2 0.02, $p = 0.8830$).

When postmenopausal status was tested in the Cox model with S phase and presence of extrauterine disease, menopausal status was not an adverse prognostic factor (χ^2 0.03, $p = 0.8619$), whereas presence of extrauterine disease (χ^2 5.25, $p = 0.0219$) and S phase (χ^2 6.99, $p = 0.0082$) remained independent prognostic factors.

Fig. 6 is a plot of survival based on ploidy analysis. There is a better survival in diploid tumors, with a median survival of 78.5 months versus 35.1 months with aneuploid tumors ($p = 0.0658$). Diploid tumors

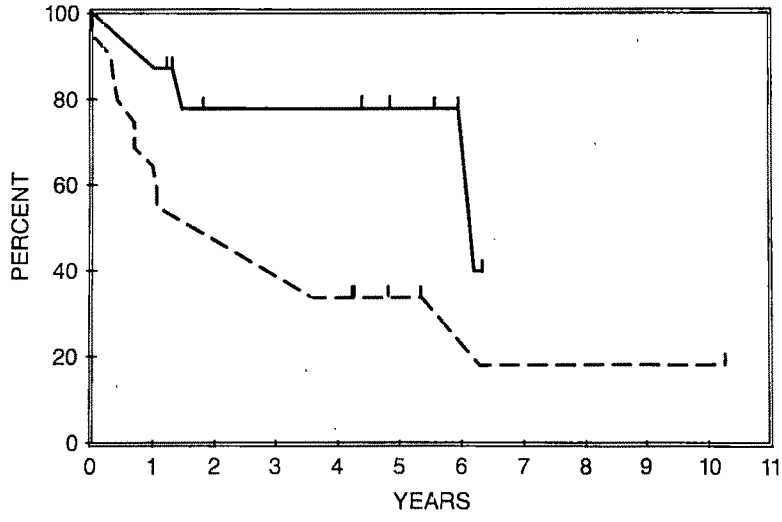

Fig. 5. Life-table survival probability by percentage of cells in S phase. *Solid line*, <10%; *dashed line*, ≥10%.

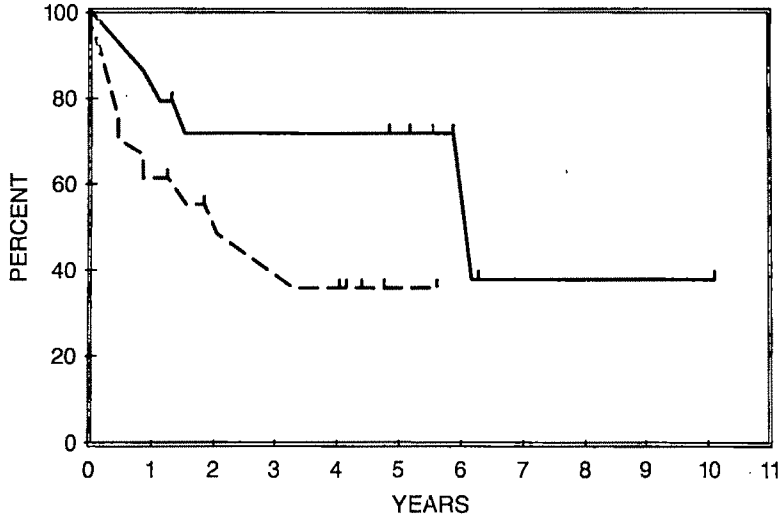

Fig. 6. Life-table survival probability by ploidy status. *Solid line*, Diploid; *dashed line*, aneuploid.

had a 70% 5-year survival and aneuploid tumors a 33% 5-year survival; however, when disease-free survival was plotted, there was no significant difference between diploid and aneuploid tumors (Fig. 7). This apparent discrepancy for survival between diploid and aneuploid tumors is explained by survival differences after recurrence, as plotted in Fig. 8. After development of a recurrence, patients with a diploid tumor have a superior survival ($p = 0.0045$).

There were 10 patients with a mitotic count of five to 10 per 10 high-power fields (Table III). None had grade 3 atypia and all were classified as tumors of uncertain malignant potential. Three of the 10 tumors were aneuploid; all three patients are alive and disease-free. Among the seven patients with diploid tumors, there have been four recurrences and one death. There is no clear-cut relationship between S phase and recurrence in these patients. When these patients have recurrence, they tend to have a more protracted course as compared with patients having leiomyosarcoma.

In an attempt to find an S-phase cutoff below which there were no recurrences or deaths, we looked separately at the 11 patients who had an S-phase total of <5%. In addition to patients 3, 7, and 8 listed in Table III, two other patients with an S phase of <5% have had recurrence. One had an S phase of 2.4% and a mitotic count of 11 per 10 high-power fields. She suffered a recurrence at 13 months and died at 36 months. The other patient had an S phase of 4.8% and a mitotic count of 12 per 10 high-power fields. A recurrence

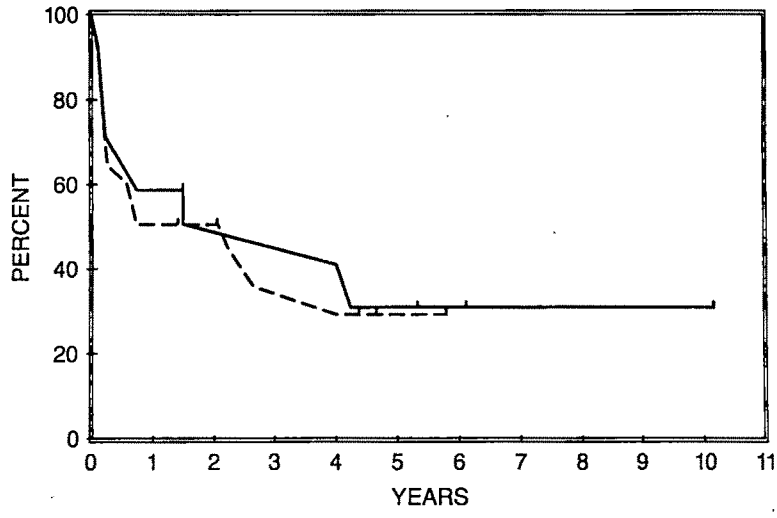

Fig. 7. Disease-free survival probability by ploidy status. *Solid line*, Diploid; *dashed line*, aneuploid.

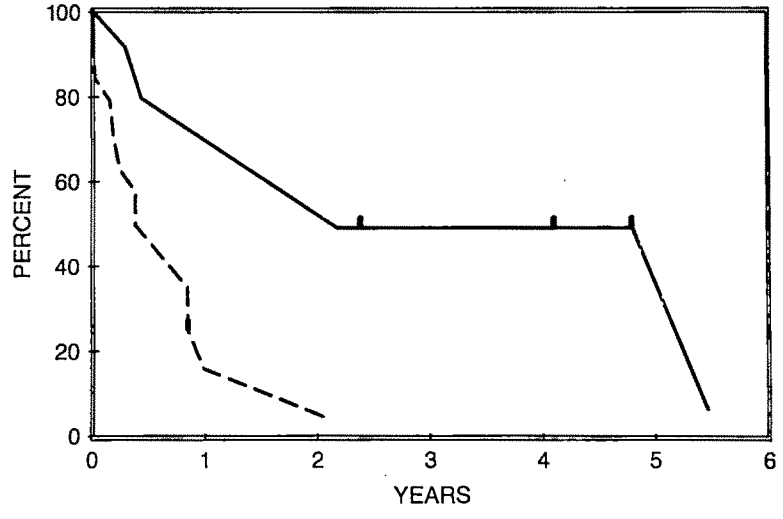

Fig. 8. Life-table survival probability from time of recurrence by ploidy status. *Solid line*, Diploid; *dashed line*, aneuploid.

developed at 53 months and she died at 77 months. Thus patients with two of the lowest three S-phase values have had recurrence. Among 11 patients who had an S phase >15%, 10 have had a recurrence.

Comment

Smooth muscle tumors of the uterus have presented problems both to the clinician and to the pathologist. Their clinical presentation is usually that of an enlarging mass, and unless there is presence of extrauterine disease, it is impossible to distinguish a sarcoma from a rapidly enlarging leiomyoma. Even the presence of extrauterine disease does not establish the diagnosis of malignancy, as there are well-documented cases of benign metastasizing leiomyomas, intravenous leiomyomatosis, and leiomyomatosis peritonealis disseminata. Clearly, there is a spectrum of disease from benign to malignant. Mitotic count has been the most consistent predictor, either alone or used in combination with atypia.[1,3,6] The criteria of Hendrickson and Kempson[7] acknowledge the uncertainty of the diagnosis and allow for a group of tumors of uncertain malignant potential. The patient's age and menopausal status also appear to have a bearing on the prognosis. Patients with postmenopausal status have generally had a poorer prognosis.[2,4,6] In our patients menopausal status was not an independent risk factor.

DNA analysis has proved useful in some but by no means all of the tumors in which it has been examined. It has become a recognized independent risk factor in

Table III. Histology and flow cytometry on 10 patients with tumors of uncertain malignant potential

Patient No.	*Age (yr)*	*Mitotic count/10 high-power fields*	*Atypia grade 1 to 3*	*Cells in S-phase (%)*	*Ploidy*	*Outcome*
1	76	5	2	3.6	Aneuploid	No evidence of disease 23 mo
2	37	5	1	4.8	Diploid	No evidence of disease 24 mo
3	51	5	1	4.8	Diploid	Recurrence 19 mo Alive with disease 74 mo
4	37	10	1	3.9	Aneuploid	No evidence of disease 61 mo
5	44	8	1	13.8	Aneuploid	No evidence of disease 53 mo
6	33	6	1	8.9	Diploid	Recurrence 3 mo Dead of disease 14 mo
7	68	8	1	3.0	Diploid	Recurrence 50 mo Alive with disease 77 mo
8	48	5	2	1.1	Diploid	Recurrence 2 mo Alive with disease 33 mo
9	39	5	1	4.1	Diploid	No evidence of disease 25 mo
10	47	5	1	6.7	Diploid	No evidence of disease 24 mo

node-negative breast cancer.[8] For uterine smooth muscle tumors Tsushima et al.[13] found a strong correlation between tumor grade and an abnormal DNA pattern. Survival was better in patients with diploid tumors, but they also found that 7% of patients classified as having benign leiomyoma had an aneuploid histogram and they cautioned that ploidy should not be used as an absolute criteria for the diagnosis of sarcoma. They did not present data on the implications of proliferative rate.

Our data underscore Tsushima's findings. Ploidy does seem to be an indicator of the aggressivenesss of the tumor. The finding of diploidy does not appear to have any ability to predict the benign versus malignant course of the disease, but once a patient had a relapse, diploid tumors tended to survive longer.

Proliferative rate (S-phase percentage) and mitotic count are strongly linked. This finding is not surprising, because both are indicators of the division rate of the individual cells. In the Cox model, S phase appeared to be the independent variable. An S phase >15% was associated with recurrence in 10 of 11 patients. Unfortunately, there was no lower level below which an S phase could be predictive of a benign course, and S-phase analysis made no contribution beyond knowledge of the mitotic count in prediction of the outcome of any individual patient. Although measurement of the S phase is an elegant test at the molecular level, mitotic count remains the gold standard for the diagnosis of leiomyosarcomas of the uterus. The effectiveness of mitotic count in classification of smooth muscle tumors probably reflects its ability to predict the proliferative rate. None of these patients had a response to either radiation therapy or chemotherapy and the only treatment modality that appeared to have any impact on their survival, once a recurrence was established, was surgical excision.

We thank Ruth Rice-Empniger, Page Kuhn, Daniel Hirschstein, and Joyce Shuck of the Laboratory of Pathology for technical expertise and efforts in performing the flow cytometry, and Tove Thompson and Janet O'Sullivan of the Puget Sound Oncology Consortium for data management and statistical analysis.

Discussion

DR. PHILIP J. DISAIA, Irvine, California. I understand that the purpose of the investigation was to study the role of flow cytometry in predicting the behavior of leiomyosarcomas of the uterus and thereby assisting the clinician in prescribing therapy. This is a laudable goal, because these lesions behave in a very precarious manner in some patients and in an indolent manner in others.

The authors cite a previous study by Tsushima et al.[1] published in 1988 addressing the same subject; however, they classified the lesions into diploid versus polyploid versus aneuploid. Indeed, they found that 59% of the leiomyosarcomas were polyploid. Peters et al. chose not to use this classification but to divide their patients into diploid versus aneuploid. One wonders whether their results would have been different had they considered looking at the polyploid group separately. Also, the authors defined the criteria for aneuploidy as follows: "DNA content was defined as aneuploid if two discreet G_0G_1 peaks were observed." I would ask the authors why they felt that two distinct G_0G_1 peaks were necessary for the classification of aneuploidy. They quoted a study by Alvegard et al.,[2] which also included so-called G_0G_1 skews and G_0G_1 broadening as aneuploids. I would ask the authors whether using their criteria resulted in excluding samples and whether broadening the criteria for inclusion might have affected the results.

The authors found no significant differences in premenopausal status between the aneuploid and the diploid tumors. With 42% containing diploids and 58% containing aneuploids, I am curious whether this would hold true with a larger sample size. The same can be said for their finding that there was no correlation between ploidy status and mitotic count ($p = 0.79$) or between ploidy status and percentage of cells in S phase ($p = 0.47$). Interpretation of p values with such small sample sizes is difficult at best.

The conclusions were consistent with those of the largest study in the literature, that of Tsushima et al.[1] We are left with a traditional way of counting mitotic figures. However, O'Connor and Norris[3] have suggested adding the observation of atypia to this calculation of mitotic figures (Table I). They studied 73 smooth muscle tumors of the uterus with five to nine mitotic figures per 10 high-power fields and concluded that mitotically active smooth muscle tumors of the uterus having five to nine mitoses per 10 high-power fields and no cellular atypia have a metastatic rate too low to be regarded as sarcomas. Follow-up of their patients from 23 months to 15 years (median 7 years) gives great importance to their conclusions. Patients with atypia or >10 mitotic figures per 10 high-power fields had the potential for metastic lesions. Until we refine the techniques of flow cytometry or have comparable technology at hand, I believe this classification should prevail.

The major criticism of this article has to do with the small sample size. This good work should be considered as a basis for a larger study, possibly by a national cooperative group, to properly test the basis of their conclusions.

Dr. Peters (Closing). A technical issue to be addressed in a flow cytometry study is how wide a coefficient of variation to accept. The answer determines whether you get narrow, sharp histograms, like the one I showed, or ones that are quite wide. One of my coauthors, Dr. Donald Howard, a pathologist, insisted on a coefficient of variation of 6, which is much smaller than many other authors have used. Doing that eliminates many wide G_0G_1 peaks that would have been classified as near aneuploid. The temptation exists to liberalize the criteria and include as many subjects as possible. Enlarging the group this way may help in statistical analysis, but, from the point of view of the molecular biologist, the data are tainted. In the case of our data we have also analyzed them with coefficients of variation of 8, 10, and 12, but the number that would be reclassified as aneuploid was fairly small.

We were surprised to find no polyploid lesions in our series; we had expected to see about 10%. Tsushima et al.[1] had a very high proportion of patients with tetraploid tumors. Although we expected to see a few in our series, we certainly did not expect to see 50%.

Menopausal status has been a significant prognostic variable in many previous series, and in our series, when we looked at it as a single variable, it did appear to be a prognostic variable. However, in the Cox model, which allows us to sort out the independent variables by multivariate regression, there was no suggestion that menopausal status was important.

Dr. DiSaia, I agree that atypia is an important diagnostic criterion in the classification system of Hendrickson and Kempson.[2] I also totally agree that some form of effective chemotherapy for these patients is needed because the end results have been so poor. We have previously presented our results of adjuvant chemotherapy of mixed mesodermal tumors with a combination of cisplatin and doxorubicin and it was quite effective.[3] Our experience with this regimen in leiomyosarcomas, however, has been dismal. We have not seen responses in patients with metastatic disease, nor do we appear to have had a prolongation of disease-free survival. We need nationwide randomized studies of other combinations.

A PILL WITH A PROGRAM

Only TRI-NORINYL starts your OC patients with The TRI-NORINYL Total Health Program.™

When you start your OC patient with The TRI-NORINYL Total Health Program sample package, you provide the benefits of oral contraception *plus* an exciting new patient-support program.

The TRI-NORINYL Total Health Program sample package contains one cycle of TRI-NORINYL; the attractive Wallette® Pill Dispenser; and a patient Q&A booklet—*plus* the video and instruction guide, *The ACOG Balanced Fitness Workout;* and program membership. The TRI-NORINYL Total Health Program provides a variety of fitness and health information to help women achieve healthier lifestyles.

As part of that goal, Syntex Laboratories is proud to be a sponsor of the American Medical Association's Women's Health Campaign.

For details about The TRI-NORINYL Total Health Program, please contact your Syntex Representative.

Serious as well as minor side effects have been reported following the use of oral contraceptives. These include thrombo-embolic disease.

Please see adjacent page for brief summary of prescribing information.

TRI-NORINYL TABLETS
(NORETHINDRONE AND ETHINYL ESTRADIOL)

ORAL CONTRACEPTIVE AGENTS: BRIEF SUMMARY

DESCRIPTION

TRI-NORINYL 21-DAY Tablets provide an oral contraceptive regimen of 7 blue tablets followed by 9 yellow-green tablets and 5 more blue tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg and each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg.

TRI-NORINYL 28-DAY Tablets provide a continuous oral contraceptive regimen of 7 blue tablets, 9 yellow-green tablets, 5 more blue tablets, and then 7 orange tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg, each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg, and each orange tablet contains inert ingredients.

INDICATIONS AND USAGE

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use these products as a method of contraception.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions: Thrombophlebitis or thromboembolic disorders • A past history of deep vein thrombophlebitis or thromboembolic disorders • Cerebral vascular or coronary artery disease • Known or suspected carcinoma of the breast • Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia • Undiagnosed abnormal genital bleeding • Cholestatic jaundice of pregnancy or jaundice with prior pill use • Hepatic adenomas, carcinomas or benign liver tumors • Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long-term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users, cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS**, section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40–49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1970s—but not reported in the U.S. until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral contraceptive use to women who do not have the various risk factors listed in this labeling.

Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular disease risks may be increased with oral contraceptive use after age 40 in healthy non-smoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception.

Therefore, the Committee recommended that the benefits of oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out.

Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING.**

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section): Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: • Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation: • Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use: • Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

The utility of immunocytochemistry in invasive adenocarcinoma of the cervix

Hisham K. Tamimi, MD,[a] Allen M. Gown, MD,[b] Jessie Kim-Deobald, MD,[a] David C. Figge, MD,[a] Benjamin E. Greer, MD,[a] and Joanna M. Cain, MD[a]

Seattle, Washington

OBJECTIVES: The purpose of the study was to evaluate the utility of immunocytochemistry in the management of cervical adenocarcinoma. Patterns of reactivity to various immunocytochemical markers were correlated with clinically known risk factors for recurrence.

STUDY DESIGN: A retrospective evaluation of 55 patients with invasive cervical adenocarcinoma was conducted. Monoclonal antibodies were generated against various human intermediate filament proteins and tested on fixed, paraffin-embedded tissue by the avidin-biotin complex immunoperoxidase method. Dako V9 antivimentin antibodies and two anticytokeratin antibodies, 35βH11 and 34βE12, were used. Polyclonal antibodies to carcinoembryonic antigen and antibodies to epithelial membrane antigen were used.

RESULTS: Of 55 patients, 50 (91%) had positive epithelial membrane antigen antibodies in tumor cells. Tissue from patients with cervical adenocarcinoma demonstrated positivity for 35βH11 antibodies in 46 of 53 patients (87%) and positivity for 34βE12 antibodies in 15 of 54 patients (28%). Vimentin antibodies were negative in all except one patient. Carcinoembryonic antigen–positive antibodies were detected in 37 of 55 patients (67%). This study also demonstrated consistent negative expression of vimentin in invasive cervical adenocarcinoma. Carcinoembryonic antigen expression rates were 50% and 75% for patients with small tumors (≤2 cm) and large tumors (>2 cm), respectively ($p < 0.01$). Patients with carcinoembryonic antigen expression are at increased risk for recurrence and also sustain reduced survival potential.

CONCLUSIONS: Patients with cervical adenocarcinoma and carcinoembryonic antigen expression are at increased risk for recurrence. We speculate that immunocytochemistry may detect lymph node micrometastases otherwise unsuspected by conventional microscopy. (Am J Obstet Gynecol 1992;166:1655-62.)

Key words: Immunocytochemistry, cervical adenocarcinoma

The diagnosis of invasive adenocarcinoma of the cervix as a distinct clinical entity poses special problems for the epidemiologist, pathologist, surgeon, and radiotherapist. Several reports have observed an increasing incidence of adenocarcinoma of the cervix,[1-3] particularly in the last three decades. It is unknown whether this is an absolute or relative increased incidence. The effectiveness of conservative outpatient therapy for squamous cell cervical intraepithelial neoplasia may have resulted in increased relative incidence of cervical adenocarcinoma as compared with invasive squamous cell carcinoma. There is a disproportionately higher incidence of adenocarcinoma among patients with development of invasive cervical cancer after unsuccessful outpatient treatment for cervical intraepithelial neoplasia.[4] Moreover, cytologic screening for detection of invasive cervical adenocarcinoma has proved less than satisfactory.[5]

Classifications of adenocarcinoma of the cervix have been introduced in an attempt to assign risk factors related to the histopathologic diagnosis. Several observers have concluded that patients with the diagnosis of adenosquamous and poorly differentiated adenocarcinoma[6, 7] are probably at higher risk for recurrence and hence sustain lower survival rates. Histochemical studies, such as mucin stains, have failed to define a marker that can reliably distinguish between an endocervical and endometrial primary tumor.[8] Current interest in immunocytochemistry, however, has reawakened interest in this distinction, and it has been demonstrated that antibodies to vimentin, intermediate filament protein, provide an immunocytochemical tool that enables the pathologist to distinguish between adenocarcinoma of the uterine cervix and adenocarcinoma of the endometrium.[9] Mammalian cells contain three classes of cytoplasmic filamentous structures: mi-

crofilaments, microtubules, and filaments of intermediate diameter. Intermediate filaments are divided into various subclasses on the basis of biochemical analysis and immunochemical reactivity.[10, 11] Cytokeratins are the intermediate filaments present in epithelial cells; mesenchymal cells contain the intermediate filament protein vimentin. Desmin, glial fibrillary acidic protein, and neurofilaments are other examples of intermediate filament subclasses. Intermediate filament proteins may be used as markers to identify specific cell types in benign or malignant tumors. Malignant cells, in general, contain the same intermediate filament class as in corresponding normal tissue.[12] Monoclonal or polyclonal antibodies generated against the various human intermediate filament proteins can be used in deparaffinized sections or formalin-fixed tissues.

The purpose of this report is to determine the utility of immunocytochemistry in detecting tissue cell markers in 55 patients with cervical adenocarcinoma and to correlate the clinical aspects of this disease with the various immunocytochemical findings. The following immunocytochemical proteins were used: vimentin, cytokeratin 8 (low-molecular-weight cytokeratin), high-molecular-weight cytokeratin, carcinoembryonic antigen, and epithelial membrane antigen.

Material and methods

The files of the Division of Gynecologic Oncology at the University of Washington Medical Center were reviewed. During the 10-year period from 1976 through 1985, 88 patients with the diagnosis of invasive cervical adenocarcinoma and its subtypes were identified. Patients with the diagnosis of adenocarcinoma in situ were not considered in this study. The cases included in the study had tissue blocks from radical hysterectomies, total abdominal hysterectomies, total pelvic exenterations, or cervical biopsies. Thirty-three of the 88 patients were excluded from the study because of lack of suitable histologic material. In 21 instances outside hospital surgical specimens were not available. In three instances no tumor remained after processing, and in nine cases the tissue available proved unsuitable for immunocytochemical study, because of either inconsistent immunostaining or poor antigenic preservation of the specimen. Fifty-five cases were thus included in the study.

All surgical specimens had been previously fixed in formalin and paraffin embedded in blocks. In 10% of the cases a portion of the tissues had also been fixed in methacarn.

Sections measuring 5 μm were deparaffinized in xylene and rehydrated in a series of graded alcohol incubations. Serial sections of each case were then incubated with a panel of monoclonal antibodies consisting of 35βH11, an anticytokeratin 8 antibody; 34βE12, an anticytokeratin monoclonal antibody[13]; V9, an antivimentin monoclonal antibody; E29, an antiepithelial membrane antigen monoclonal antibody; and a rabbit polyclonal antibody to carcinoembryonic antigen. All antibodies were obtained from, or are available from, Dako Corporation (Carpinteria, Calif.). In the case of 35βH11 and 34βE12 only, predigestion of the tissue sections before antibody incubation was required (20 minutes of 0.01% pronase in phosphate-buffered saline solution [Calbiochem, La Jolla, Calif.] and 10 minutes of 0.05% Type II trypsin [Sigma, St. Louis] in 0.05 mol/L Tris buffer, pH 7.6, respectively). All antibody localization was by a modification of the avidin-biotin immunoperoxidase technique, as described,[13] in which nickel chloride is added to the chromogen, 3,3′-diaminobenzidine, to yield a black reaction product.

The hospital records of the 55 patients involved in the study were reviewed for age, parity, method of contraception, stage, grade, histologic type, symptoms, vaginal cytologic results, presence or absence of gross lesion, survival, follow-up duration, recurrence, primary therapy, grade of tumor, lesion size, depth of penetration, nodal metastases, number of metastatic nodes, associated cervical intraepithelial neoplasia, and adjuvant therapy. To maintain consistency in estimating tumor size, the measurements were obtained from pathologic evaluation when possible. In patients receiving preoperative irradiation, the measurements were estimated from clinical data. The minimum follow-up duration was 60 months. A $p < 0.05$ was considered statistically significant.

Results

Clinical profile. The mean age of the patients in the study was 39.6 years and the median age was 37 years. Forty-one of the 55 patients were treated by radical hysterectomy and bilateral lymphadenectomy; these patients form a subgroup that yielded more precise information regarding depth of invasion and metastatic spread. These patients were also slightly younger, with a mean age of 36.1 years and a median age of 36 years. Parity ranged from nulliparity to para 8, with a mean of 2.5 and a median of 2.

The stage of the cervical cancer was determined according to the International Federation of Gynecology and Obstetrics staging system as revised in 1988. None of the cases were considered microinvasive. Forty-five were stage IB, five stage II, two stage III, and three patients had recurrent or persistent disease after initial therapy performed elsewhere.

Adenocarcinoma was the histologic diagnosis in 43 of the patients, adenosquamous in 10, mesonephric (wolffian duct) adenocarcinoma in one, and poorly differentiated papillary adenocarcinoma in one. Bleeding was the most common symptom and was experienced in 36 (65.45%) of cases. Eighteen (32.73%) denied any presenting symptom, and one patient complained of excessive vaginal discharge.

Table I. Immunocytochemical analysis of various antibodies

Antibody	Positive tumor staining		Positive internal control	
	No.	%	No	%
Anticytokeratin				
35βH11	46/53	87	48/53	91
34βE12	15/54	28	45/52	85
Antivimentin	01/54	1.8	42/55	76
Anti-carcinoembryonic-antigen	37/55	67	49/53	92
Anti-epithelial-membrane-antigen	50/55	91	55/55	100

Table II. Age versus immunocytochemical markers

	Mean age (yr)	
	Positive	Negative
Carcinoembryonic antigen	39.1	42.1
Low-molecular-weight cytokeratin 8	39.2	44.5
High-molecular-weight cytokeratin	37.7	40.7
Vimentin	37.0	40.2
Epithelial membrane antigen	39.4	47.2

An atypical vaginal cytologic result was present in 38 instances (69.1%).

A gross lesion was present in 35 (64.6%) of the patients, whereas in 20 instances (36.4%) no detectable gross lesion was present. The diameter of the primary lesion was >2 cm in 30 patients (54.55%) and was ≤2 cm in 24 (43.64%). In one patient the size of the initial lesion could not be determined.

An improved outcome was observed in patients with invasion less than one half of the cervical stroma. The majority (24/25), including one patient with positive nodes, survived with no evidence of disease. Only one patient had recurrent disease. Patients with deep cervical invasion (greater than the inner half) experienced poor outcomes; eight of the 16 (50%) died of cancer, and lymph node metastases were observed in four of 16 (25%).

The depth of invasion was more accurately determined in the subgroup of 41 patients treated by radical hysterectomy. Twenty-five of these 41 cases had invasion of less than one half the cervical stroma, whereas the remaining 16 had deeply penetrating tumors. Disease had extended beyond the cervix in four instances.

The histologic type was designated as grade 1 in 27 (49%) of the patients, grade 2 in 14 (25.5%), and grade 3 in 14 (25.5%). Nodal metastases were detected in 10 patients (18.28%) of the entire group and in five (12%) of those treated by radical hysterectomy.

Squamous cervical intraepithelial neoplasia was also present in association with the primary adenocarcinoma in 12 patients. Six of these were associated with adenosquamous carcinomas. Two of them had positive nodal metastases, and one of these had a recurrence, resulting in death. In contrast, 25 patients had no evidence of cervical intraepithelial neoplasia. Two were initially diagnosed with adenosquamous carcinoma and three had positive lymph node metastases; six died of cancer.

The median follow-up of patients was 56 months, with a range of up to 120 months. One patient has been lost to follow-up shortly after a radical hysterectomy was performed for stage I disease and one patient died of a massive pulmonary embolus after surgery. Of the remainder, 16 (30%) are dead of disease and 37 (70%) were free of disease at the time of last examination. Twenty-two percent of those treated by radical hysterectomy failed to survive. Recurrent disease proved to be a most ominous finding. Of 17 patients in whom such a recurrence developed, only one is still alive and free of disease after a total pelvic exenteration for a central pelvic recurrence.

Immunocytochemistry. Reactivity of <10% of the tumor cells was considered negative. Most of the cases designated as positive with the various antibody markers showed immunoreactivity in >50% of the tumor cells.

For the anticytokeratin, carcinoembryonic antigen, and epithelial membrane antigen studies immunostaining of the normal squamous and glandular epithelium served as an additional internal control. No such reactivity was present in four cases. An additional four cases were nonreactive with antivimentin antibodies in the connective tissue and vascular endothelium. Either no normal tissues were present on the slides in these cases or the tissues present were nonreactive. In one case anticytokeratin antibody 35βH11 and antivimentin were not demonstrated because the slides contained no tumor cells, either because of loss of the tumor tissue during processing procedures or the actual absence of tumor cells.

Table I is a summary of the results of various antibody studies. There was no significant difference in the frequency of positive staining within the control groups with anticytokeratin 35βH11 and 34βE12. Eighty-seven percent of cases were positive with antibodies to 35βH11 but only 28% with antibodies to 34βE12. With antivimentin the corresponding tumor cells reacted in only one instance. The tissue diagnosis in this single case was poorly differentiated papillary variant of cervical adenocarcinoma without endometrial involvement. It behaved as a very aggressive neoplasm. Carcinoembryonic antigen was positive in 92% of the control slides but in only 67% of the tumor tissue.

Table II looks at the immunocytochemical results as a function of patient age. Although there were no significant differences between the two groups, patients with a negative staining reaction were consistently older than those with a positive reaction. This difference was

particularly apparent in epithelial membrane antigen (47.2 vs 39.4 years).

Table III details the distribution of positive staining to immunocytochemical markers with respect to the histopathologic diagnosis. The majority of cases were diagnosed merely as adenocarcinoma. Ten patients had adenosquamous carcinomas. One was defined as an adenocarcinoma of mesonephric origin and another as a papillary serous carcinoma. Forty-four of the 55 patients (80%) had stage IB lesions. The numbers in clinical stages beyond IB were too small to permit a statistical evaluation, but no significant differences in tissue reactivity could be seen between the various stages.

Table IV is a comparison of tumor size and the antigenic profile of the tumor in 54 patients; tumor size was designated as >2 or ≤2 cm in maximum dimension. Although the presence of epithelial membrane antigen and the various cytokeratins proved to be of no significant difference between the two groups, carcinoembryonic antigen expression was present in only 50% of patients with small tumors but in >75% of cases with tumors >2 cm. This difference is significant with $p < 0.01$.

Table V is a comparison of immunocytochemical markers in patients who survived without evidence of disease and those who died of disease. One patient was lost to follow-up and another died postoperatively. Expression of carcinoembryonic antigen was demonstrated in 11 of 16 patients who died of disease and in 26 of 37 who have no evidence of disease.

The 41 patients treated surgically by radical hysterectomy and bilateral lymphadenectomy represent a large and relatively homogeneous group with many similar clinical characteristics. They may be appropriately divided into two groups; group 1 consisting of 21 patients whose tumor measured ≤2 cm and group 2 consisting of 20 patients whose tumor diameter was >2 cm. In each group the response to the immunocytochemical markers together with several clinical pathologic factors is summarized in Table VI. The difference in expression of carcinoembryonic antigen between the two groups does approach statistical significance ($p = 0.058$). Group 1 clearly demonstrated an improved outlook. The majority of these patients (18/21) had grade 1 lesions, although five had the adenosquamous variant. Although no patient in this group had lymph node metastases, two of the 21 did have recurrence. The remainder (19/21) clinically have no evidence of disease. Among the patients in group 2 with larger lesions, 45% showed grade 3 histologic type, five of the 20 (25%) had lymph node metastases, and recurrent disease developed in seven instances (35%).

Table V. Status versus immunocytochemical results

Status	No.	*Low-molecular-weight cytokeratin (n = 52)*		*High-molecular-weight cytokeratin (n = 53)*		*Carcinoembryonic antigen (n = 54)*		*Vimentin (n = 53)*		*Epithelial membrane antigen (n = 54)*	
		Positive	*Negative*	*Positive*	*Negative*	*Positive*	*Negative*	*Positive*	*Negative*	*Positive*	*Negative*
No evidence of disease	37	30	5	10	26	26	11	0	36	33	4
Dead of disease	16	15	1	4	12	11	5	1	15	15	1
Dead of concomitant disease	1	0	1	1	0	0	1	0	1	1	0

Two of the patients with nodal metastases remain free of disease, but it is noteworthy that among the nine cases of recurrent carcinoma four patients had negative lymph nodes.

Comparable data were observed in patients with a depth of invasion greater than or lesser than one half the depth of the cervical stroma. Twenty-five of 41 patients demonstrated depth of invasion of less than one half of the cervical stroma with carcinoembryonic antigen–positive reactivity in 17 instances (68%). Anticytokeratin 34βE12 stained positively in nine patients. In 16 patients the depth of invasion exceeded the inner one half of the cervical stroma, and positive carcinoembryonic antigen was expressed in 10 cases (62.5%). This included four patients in whom the tumor extended beyond the cervix. All of these cases were positive for carcinoembryonic antigen.

Sixteen patients who used oral contraceptives before the diagnosis of adenocarcinoma were compared with 13 patients who denied any contraceptive practice. The patterns of carcinoembryonic antigen immunostaining were significantly different between the two groups. The tumors showed carcinoembryonic antigen expression in 14 of the 16 using oral contraceptives although in only seven of the 13 who denied contraceptive use. This difference is statistically significant ($p = 0.04$), although the explanation is not readily apparent. Moreover, in the group that used oral contraceptives only one of the 16 had nodal metastases and the survival rate was 86% (12/14). Among those who did not use contraception there were six instances of nodal disease and the corresponding survival rate was only 61% (8/13).

Comment

Several investigators have confimred the value of immunocytochemistry in distinguishing between primary adenocarcinoma of the cervix and stage II adenocarcinoma of the endometrium with cervical extension. Vimentin expression by endometrial adenocarcinoma but not by cervical adenocarcinoma is now recognized as the most reliable marker in resolving this confusion.[9]

Table VI. Summary of clinicopathologic and immunocytochemical findings in 41 patients treated by radical hysterectomy

	Disease ≤2 cm (n = 21)	*Disease >2 cm (n = 20)*
Positive immunocytochemical marker

Recurrence	2 (9.5%)	7 (35%)
No evidence of disease	19 (90%)	12* (60%)

*One death after postoperative massive pulmonary embolus.

There is, however, very limited information available to use on long-term follow-up of patients with cervical adenocarcinoma analyzed by contemporary immunohistochemical staining with a panel of markers.

Wahlstrom et al.[14] have reported on differences in the distribution of anti–carcinoembryonic antigen immunostaining between adenocarcinoma of the endometrium and endocervix. Endometrial adenocarcinoma was positive in only 8% of the cases stained, whereas endocervical adenocarcinoma was positive in 80%. Our observation that 69% of patients with cervical adenocarcinoma expressed carcinoembryonic antigen correlates well with the findings of others.[8, 15] The correlation between tumor size and positivity of carcinoembryonic antigen immunostaining is also of interest. Van Nagell et al.[16] have reported on plasma determination values of carcinoembryonic antigen in patients with cervical cancer. They concluded that the absolute carcinoembryonic antigen level appears related to tumor burden as measured by tissue concen-

tration and the extent of disease. There was a direct correlation with recurrent cancer in >80% of their patients. However, the analysis of Van Nagell et al. was derived predominantly from patients with squamous cell carcinoma. In 25 patients with cervical adenocarcinoma, only nine (36%) proved to have positive results for carcinoembryonic antigen. Our findings do suggest that patients with carcinoembryonic antigen expression are at an increased risk for recurrence and also sustain a reduced survival potential. Among such patients serial carcinoembryonic antigen plasma values might be of value in the effort to detect recurrent disease at an early stage. It should be emphasized that the level of reactivity in immunologic staining reflects the extent of cellular proliferation rather than merely the presence of malignancy.

Several studies have confirmed the significance of lymph node metastases as a major risk factor for recurrence in cervical cancer.[17-20] Our report also observed that six of nine patients with recurrent stage IB disease had no evidence of nodal spread as determined by conventional microscopic assessment. Immunocytochemistry has been used to detect micrometastases in bone marrow among patients with breast[21] and ovarian[22] cancers, and immunocytochemical staining in the bone marrow has proved predictive of recurrence in such patients. Immunocytochemistry has improved detection of axillary lymph node micrometastases in patients with breast cancer. It would seem reasonable to suggest that the same technology might be appropriate in adenocarcinoma of the cervix and that we should not restrict our approach to conventional microscopy. Among those patients with carcinoembryonic antigen–positive tumors, carcinoembryonic antigen immunostaining of the lymph nodes might reveal otherwise unsuspected nodal spread and serve as a foundation for adjunctive therapy in an effort to minimize the incidence of local or regional failure.

One of the current challenges in gynecologic oncology is to distinguish those patients at high risk for tumor recurrence and to detect such recurrent disease at an earlier time. It is quite possible that in the future the use of a panel of various tumor markers might allow us to distinguish such a group of patients who would benefit from additional observation, surveillance, or therapy. Serial monitoring of serum in the postoperative, postirradiation, and postchemotherapy phases of patient treatment might prove a significant addition to our pattern of surveillance. Certainly, at the present time carcinoembryonic antigen would appear to be an excellent candidate.

The substantial mortality among patients with recurrence of cervical adenocarcinoma emphasizes the need for continuing research into the epidemiologic characteristics, pathogenesis, presentation, and therapy of this disease. Success in achieving control over cancer must finally depend on our ability to shed light on the natural history of malignancy. It is quite possible that the use of serial markers, particularly the more recently acquired agents, may help us to understand the evolution of endocervical columnar atypia[23] or dysplasia or to define the biologic behavior of endocervical glandular tumors of the so-called minimal deviation adenocarcinoma.[24-26] Immunocytochemistry can offer us an additional tool for such investigations and should be exploited in every direction.

Discussion

DR. GLEN E. HAYDEN, Seattle, Washington. Several important clinical points require emphasis. Vigorous endocervical curettage is a necessary step in the diagnosis of grade 2 cervical intraepithelial carcinoma because adenocarcinoma of the cervix is frequently associated with it. Cytologic screening for early diagnosis of cervical adenocarcinoma is not highly effective. The authors' data indicate that outcome closely follows the depth of invasion; when less than one half of the endocervix is involved, the outcome is favorable. Interestingly, patients using oral contraceptives had a better outcome regardless of the stage. Oral contraceptives also reduce the incidence of endometrial carcinoma, and in that disease the outcome is improved if the patient has been receiving estrogen therapy.

The most important part of this presentation is the lack of expression of vimentin in 54 of 55 lesions of the endocervix. The authors' ability to distinguish between endocervical and endometrial carcinoma was well demonstrated. The single specimen with the positive monoclonal antibody test result for vimentin has several possible explanations; endometrial cell contamination is the more likely and the rare endometrioid lesions, either primary or secondary from the ovary, is the less likely.

Anti–carcinoembryonic antigen immunostaining also predicts outcome for endocervical lesions, particularly the more extensive lesions. The presence of carcinoembryonic antigen staining strongly suggested a poorer prognosis. Immunocytochemistry may be of value in the future as an additional method for surveillance and monitoring of therapy.

DR. WILLIAM A. PETERS III, Seattle, Washington. It is often difficult to distinguish a stage I adenocarcinoma of the cervix from a stage II carcinoma of the endometrium. The technique that we have come to rely on in making this distinction is magnetic resonance imaging which has been reliable although quite expensive. The vimentin antibody test is a more direct way of getting the information and may eliminate the need for magnetic resonance imaging in many patients.

We are seeing increased numbers of patients with adenocarcinoma in situ, and the distinction from early invasive adenocarcinoma of the cervix is frequently very difficult to make. Dr. Tamimi, have you looked at specimens from patients with adenocarcinoma in situ and from patients with early stromal invasion? If so, have you found immunocytochemistry to be of any benefit in making the distinction?

DR. PHILIP J. DISAIA, Irvine, California. Carcinoembryonic antigen, a fetal oncogene, is probably expressed by the mechanism of derepression. Did you correlate carcinoembryonic antigen with tumor grade? Did you see it more commonly in high-grade tumors? Dr. Peters has alluded to the possibility of using carcinoembryonic antigen as a diagnostic tool to differentiate adenocarcinoma of the endometrium that secondarily involves the cervix rather than adenocarcinoma of the cervix that involves the endometrium. How quickly can you do this test? Is it really available within days so that it is useful to the clinician?

DR. WILLIAM LUCAS, Ashland, Oregon. We at the University of California, San Diego, like many other oncology groups around the world, started to notice an increase in the incidence of adenocarcinoma relative to other histologic types of cancer of the cervix in the early 1980s. When there appears to be a significant shift in histologic types, it seems to me that some environmental factor is operating. Do you have any ideas about epidemiologic studies that might identify those factors so that we would perhaps have a better chance at prevention? Dr. Hayden referred to the possible protective effect of oral contraceptives. I wonder if the conclusion might be premature until we make sure that endocrine factors are not operative in increasing the incidence of adenocarcinoma of the cervix. Although cervical adenocarcinoma associated with oral contraceptives may be a more benign disease, as is estrogen-associated endometrial adenocarcinoma, we need to be sure that an analogous situation does not exist for inducing cervical adenocarcinoma.

DR. TAMIMI (Closing). Dr. Hayden asked whether the finding of a positive vimentin stain in the single patient was contamination or an error in diagnosis. I do not think that it was an error in diagnosis because we looked at this case carefully in terms of the histologic type and clinical course. It was a poorly differentiated adenocarcinoma of the cervix limited to the cervix and was

not an endometrial cancer. Thus this was a positive vimentin test in an adenocarcinoma of the cervix. There have recently been reports of coexpression of vimentin in breast cancers.[1-3] These investigators reported on very anaplastic tumors and considered vimentin to be a prognostic marker. We think that positive vimentin coexpression indicates an anaplastic tumor with a very aggressive clinical course. We happen to have seen only one case so far, but I suspect that as we continue to look for it we will find more.

Dr. Peters, we looked at the immunochemical results of invasive adenocarcinoma only, not adenocarcinoma in situ.

Dr. DiSaia, you asked why the carcinoembryonic antigen level is high in our subjects. This finding does not differ from that in other studies. For example, Wahlstrom et al.[4] reported an 80% incidence of positive carcinoembryonic antigen. You also asked about the time it takes to obtain results after the immunocytochemistry tests. Within 3 days of the request we obtain results of cytokeratin, vimentin, and carcinoembryonic antigen. For patients with malignancy we are now also looking at oncogenes, P53, and growth factors.

Dr. Lucas, I do not know whether oral contraceptives are related to the increased incidence of cervical adenocarcinoma. Patients who are exposed to oral contraceptives and have adenocarcinoma of the cervix tend to have had long-term exposure, 5 to 10 years. To answer this question will require in-depth epidemiologic studies.

Advanced epithelial ovarian carcinoma: Long-term survival experience at the community hospital

Ronald F. Unzelman, MD
Santa Rosa, California

OBJECTIVE: The purpose of this study was to determine prognostic factors that could be altered to increase survival of patients with advanced ovarian cancer treated at the community hospital.
STUDY DESIGN: This study is a retrospective analysis of 101 patients with stage III and IV epithelial ovarian carcinoma who underwent primary surgery at two private hospitals from 1970 to 1990.
RESULTS: Primary laparotomy was done by a general surgeon in 54 cases. The tumors in 23% of stage IIIC cases were debulked to ≤2 cm residuum. The survival rate decreased as stage or postoperative tumor residual increased. Patients with stage IIIA and IIIB disease had similar survival rates, significantly better than those with stage IIIC disease. Cytoreduction of stages IIIB and IIIC to microscopic disease resulted in a survival curve equal to the "natural optimal" stage IIIA. Patients with cytoreduction of stage IIIC disease to ≤2 cm did not obtain survival rates equal to those with stage IIIB disease with visible tumor remaining. Patients with stage IIIC disease achieved a significant increase in survival rate if their tumors were cytoreduced to microscopic disease. Platinum-based combination chemotherapy compared with alkylating agents improved survival in patients with stage IIIC disease who had >2 cm tumor residual. Seven patients survived >5 years, with three patients currently free of disease. Three prognostic categories predict decreasing survival: (1) stage IIIC if tumor is cytoreduced to no visible residual, stage IIIA or stage IIIB; (2) stage IIIC with visible tumor residual; (3) stage IV.
CONCLUSION: Survival of community hospital–treated advanced ovarian carcinoma patients can be improved by early diagnosis, adjuvant platinum-based combination chemotherapy, and surgical cytoreduction to minimal disease. This treatment requires a team approach and education of the medical staff, including nongynecologists. (Am J Obstet Gynecol 1992;166:1663-72.)

Key words: Ovarian carcinoma, survival rate, chemotherapy, residual tumor

Ovarian cancer is a devastating disease. It was estimated that in 1991 there would be 20,700 new cases of ovarian cancer in the United States. This represents 29% of all new cases of genital organ cancer in females. Most patients present with advanced stage disease, and prognosis is poor. For 1991 12,500 deaths from ovarian cancer are estimated; this amounts to 53% of the expected deaths from all female genital cancer, placing ovarian cancer as the fifth most common cause of cancer death among women in the United States.[1]

Staging categories for primary carcinoma of the ovary are based on findings at surgical exploration. In 1985 the Oncology Committee of the International Federation of Gynecology and Obstetrics (FIGO) changed the definition of stage III cancer of the ovary. Stage III is now subdivided into categories A, B, or C on the basis of the size of the peritoneal implants outside the pelvis or positive retroperitoneal or inguinal lymph nodes (Table I).[2]

It was believed that a retrospective study of advanced-stage epithelial ovarian carcinoma in a suburban northern California city could give useful information concerning patients who are operated on in local community hospitals. Long-term survival and prognostic categories could be refined by the new staging system and added to the literature of ovarian cancer derived in the United States, mostly from referral university medical centers. It has been suggested that specialist cancer units acting as tertiary referral centers may well attract a biased population.[3]

Material and methods

Cases were chosen from two private hospitals in Santa Rosa, California, Santa Rosa Memorial Hospital and Warrack Hospital, for the period Jan. 1, 1970, to Dec. 31, 1990 (records for the first 2 years of the study were not available from Warrack Hospital). The city of Santa Rosa is 50 miles north of San Francisco; it had a population of 50,000 in 1970 (14.8% ≥65 years of age) and 112,000 in 1990 (16% ≥65 years of age). Santa Rosa Memorial Hospital is a 225-bed, not-for-profit, religious-sponsored hospital that had 220,415 inpatients

Table I. FIGO definition of stage III and IV carcinoma of the ovary

Stage III.	Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastasis equals stage III. Tumor is limited to the true pelvis, but with histologically verified malignant extension to small bowel or omentum.
Stage IIIA.	Tumor grossly limited to the true pelvis with negative nodes, but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces.
Stage IIIB.	Tumor of one or both ovaries, with histologically confirmed implants of abdominal peritoneal surfaces, none >2 cm in diameter. Nodes negative.
Stage IIIC.	Abdominal implants >2 cm in diameter and/or positive retroperitoneal or inguinal nodes.
Stage IV.	Growth involving one or both ovaries with distant metastasis. If pleural effusion is present there must be positive cytologic test results to allot a case to stage IV. Parenchymal liver metastasis equals stage IV.

Staging is based on findings at clinical examination or surgical exploration.

(excluding normal newborns) during the study period. Warrack Hospital is a 79-bed, acute-care, for-profit hospital that had 59,560 inpatients during the period Jan. 1, 1972, to Dec. 31, 1990. The hospitals are 1 mile apart and have similar surgical and medical oncology staffs. There is no gynecologic oncologist immediately available in the area; medical oncologists supervise chemotherapy treatment.

The inpatient discharge diagnosis list was reviewed for the study years for the two hospitals. Three-hundred-forty patients were coded as 1830 International Classification of Diseases–Clinical Modification (primary malignant neoplasm, ovary). 24 charts could not be located; therefore 316 charts were reviewed. The criteria for inclusion in the study required the patient to have stage III or IV primary epithelial ovarian carcinoma diagnosed by initial laparotomy at either hospital during the above study period. Two hundred fifteen cases did not meet the criteria. One case of primary peritoneal carcinoma was excluded. Not included in the analysis are 103 patients who had initial surgery elsewhere, 19 patients with presumed diagnosis of ovarian cancer but who did not have surgery, 2 patients with initial surgery before 1970, and 36 patients who did not have invasive primary epithelial ovarian adenocarcinoma. Of the 103 other hospital cases, 12 were noted to have had primary surgery by referral from Santa Rosa to a medical center. The 155 cases of primary epithelial ovarian cancer operated on at the study hospitals were staged by retrospective chart review. Forty-seven were stage I and seven were stage II (note that only three of these stage II had omental biopsies). The 101 cases staged as III and IV comprise the basis for this report, representing 65% of the primary ovarian epithelial carcinomas. Seventy-seven patients had initial surgery at Memorial Hospital and 24 at Warrack. When appropriate, cases were discussed with the primary surgeon or primary care physician and available outpatient records were reviewed. Residual tumor after primary surgery was coded by the diameter of the largest remaining nodule and subdivided into nonvisible (microscopic), ≤2 cm, or >2 cm. Estimation of residual tumor from the operative note was not possible in one stage IIIC patient operated on in 1970 who survived 4 months after receiving postoperative irradiation. Data were also gathered on potential independent prognostic factors as follows: postoperative adjuvant therapy, age of patient at primary surgery, parity, speciality of primary and assistant surgeons, histologic characteristics and grade of tumor, ascites, and whether the patient had had a prior hysterectomy. Patient performance status as a prognostic variable could not be evaluated because the hospital charts did not contain sufficient information to retrospectively assign a Karnofsky index. Percentages are not given for occurrences related to the entire patient population because the number of cases will essentially equal percent if the denominator is 101.

Survival curves were prepared with the Kaplan-Meier method.[4] Survival was defined as months from primary surgery to date of death. Tic marks were placed on the survival curves to represent the follow-up times of patients alive as of Dec. 31, 1990. Deaths were checked with local death certificates, and all patients who died did so with disease. Results are reported as 5-year and median survival rates.

The log-rank test was used to compare survival curves by obtaining a χ^2 value. Statistical significance was considered at $p < 0.05$. When categories of a prognostic variable followed an expected ordering such as stage, a test for linear trend of survival was used to report the overall significance of that variable. Analysis for the χ^2 was done within prognostic strata when appropriate according to the method of Peto et al.[5]

Results

The median age at primary surgery was 65 years 6 months (mean age 64 years 2 months), with a range from 33 years 5 months to 88 years 10 months. There were 9 patients <45 years of age, 36 >70 years, and 19 patients >75 years. No significant difference in survival curves could be demonstrated for age groupings even if divided at 5-year intervals from 45 to 75 years.

Review of the operative findings at primary surgery

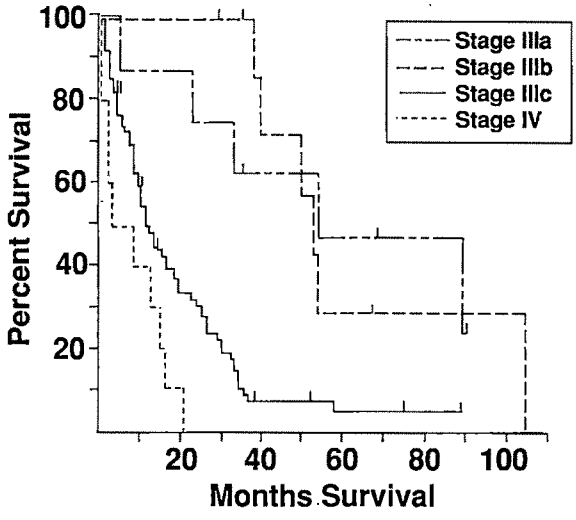

Fig. 1. Survival by FIGO stage. Chi-square test for trend yielded 21.2; $p < 0.001$. p values for individual curves: IIIA vs IIIB, not significant; IIIB vs IIIC, 0.001; IIIC vs IV, <0.025.

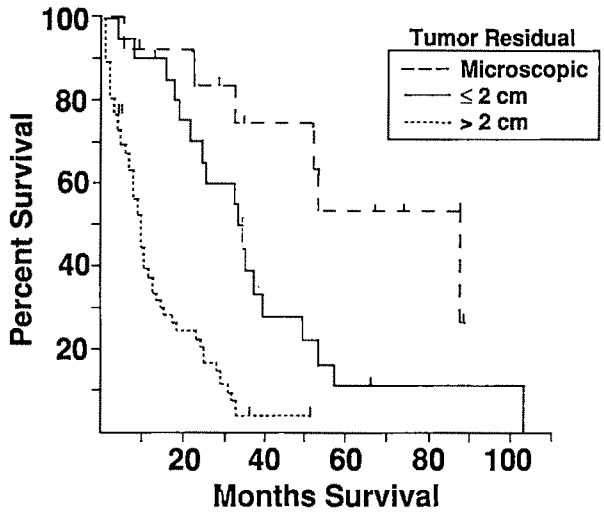

Fig. 2. Survival according to the largest tumor residual after primary surgery in patients with stage III disease. X^2 for trend yielded 28.8; $p < 0.001$.

according to the latest FIGO staging classification yielded 8 stage IIIA, 9 stage IIIB, 74 stage IIIC, and 10 stage IV cases. Survival according to stage is shown in Fig. 1. Five-year/median survival rates are as follows: stage IIIA, 47%/50 months; stage IIIB, 29%/51 months; stage IIIC, 5%/11 months; stage IV, 0%/3 months. Fig. 2 shows survival curves for stage III patients based on the tumor left in the abdomen after primary surgery. Five-year/median survival rates are as follows: microscopic (n = 13), 53%/58 months; ≤2 cm (n = 21), 11%/34 months; >2 cm (n = 56), 0%/9 months.

Initial surgical procedures are listed in Table II. Only 43 patients had complete removal of uterus, tubes, and ovaries. Bowel surgery included 4 small bowel resections, 2 large bowel resections, 3 internal bowel bypass procedures, and 2 colostomies. In six cases the abdominal incision was a low transverse Pfannenstiel. No patient had pelvic or periaortic lymph node sampling. Primary surgery resulted in the debulking of stage IIIC tumors to ≤2 cm in 23% (17 cases) for the entire series. For the years 1970 to 1979 debulking to ≤2 cm nodules was accomplished in 14% for stage IIIC tumors; for the years 1980 through 1990 this figure rose to 32%. In stage IIIC patients survival for the years 1980 through 1990 was better than for the period 1970 through 1979 (Fig. 3). Five-year/median survival rates increased from 0%/9 months to 10%/19 months, a significant difference at $p < 0.005$. The death-rate ratio of 0.48 showed that stage IIIC patients were dying at half the rate in the later years.

Six of the 101 patients died postoperatively. Table III lists the characteristics of these six patients. None had radical surgery; all six appeared to have died from the disease or predisposing cardiac factor and not from a direct complication of the surgery.

The specialty of the primary surgeon was listed as general surgeon in 54 cases, gynecologist in 46 cases, and urologist in 1 case initially seen with ureteral obstruction. In stages IIIC and IV cases the primary surgeon was a general surgeon in 48 (58%) cases and a gynecologist in 34 (40%) cases. In 23 (27%) of the 84 stage IIIC and IV cases both a gynecologist and general surgeon operated. The reverse was found for the earlier stage IIIA and IIIB cases, in which the primary surgeon was a gynecologist 71% of the time and a general surgeon 29% of the time. Both a gynecologist and a general surgeon operated together in 5 (29%) of the 17 cases of stages IIIA and IIIB disease. There was no significant difference in survival with respect to surgical specialty.

Eighty-nine patients had received postoperative adjuvant therapy. In nine cases it could be determined that no adjuvant therapy was given, and in three cases it was unknown. Three patients were irradiated and 86 received chemotherapy. Treatment with chemotherapy was divided into 59 patients who received platinum-based combination chemotherapy and 27 patients primarily treated with alkylating agents. Treatment with cisplatin (Platinol) was initiated in 1978. Cisplatin dosage was 50 mg/m²; it was used in combination with cyclophosphamide (Cytoxan) and doxorubicin (Adriamycin) until November 1987, when doxorubicin was deleted. Carboplatin (Paraplatin) has been substituted for cisplatin since 1990. The dose of carboplatin is 300 mg/m²; the combination with cyclophosphamide (600

*Patient with severe atherosclerotic cardiovascular disease.

mg/m²) is currently the protocol for initial adjuvant chemotherapy by the medical oncologists. All three of these platinum-based combinations were calculated together as platinum chemotherapy because other studies have shown the three combinations to be similar.[6-8] Until 1978 there were varied uses of melphalan (Alkeran), cyclophosphamide, and chlorambucil (Leukeran) as primary adjuvant chemotherapy. In the early years of this study six patients also received intraperitoneal triethylenethiophosphoramide (Thiotepa). Salvage therapy for progressive disease was varied with no set protocol. In recent years 10 patients with persistent intraabdominal disease have received intraperitoneal instillation of cisplatin and etoposide.

In all cases treated with chemotherapy, platinum contributed to increased survival (Fig. 4, graph A). Five-year/median survival of platinum-based combination chemotherapy ($n = 59$) versus alkylating agents ($n = 27$) were 14.9%/24 months versus 4.3%/10 months, with a death-rate ratio of 0.58. However, comparison of subgroup survival curves for platinum-based chemotherapy versus alkylating agents did not show statistically significant differences in stages IIIA, IIIB, and IV, or IIIC when tumor residual after initial surgery was ≤2 cm. Platinum-based combination chemotherapy did increase survival in the stage IIIC patients who had tumor residual >2 cm (Fig. 4, graph B). The death-rate ratio of 0.46 illustrates that platinum-based combination chemotherapy ($n = 26$) prevented or delayed about 50% of the deaths that would occur with alkylating agents ($n = 19$); median survival was 15 months compared with 9 months, but there were no long-term survivors.

The histologic characteristics and grade of the tumors are listed in Table IV. No difference in prognosis could be found in histologic characteristics or tumor grade. Combination of the two, as suggested by Dembo and Buch[9] also did not demonstrate any relationship to survival.

Sixty-four patients were recorded to have ascites at the primary surgery. Twenty-six patients had no ascites, and in 11 cases the presence of ascites was not stated. There was no significant difference in survival whether ascites was present or not.

There were 12 nulliparous women in the series. In 16 cases the parity was unknown. There was no difference in survival between parous and nulliparous patients.

Review of the medical records revealed that 35 patients had had prior hysterectomies without removal of

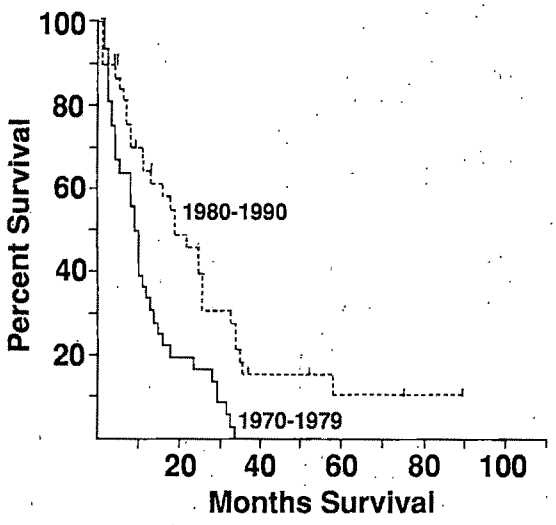

Fig. 3. Survival according to the years 1970 through 1979 (n = 36) compared with 1980 through 1990 (n = 38) for patients with stage IIIC disease. $\chi^2 = 9.6$; $p < 0.005$.

both ovaries. No difference in survival was noted for those with or without prior hysterectomy.

The presenting symptoms that most frequently brought the patient to a physician are seen in Table V. Symptoms are predominantly abdominal and not specifically pelvic in most cases. Five patients sought medical advice for abdominal masses they palpated themselves and five others for inguinal masses. Preoperative diagnoses for other abdominal conditions included bowel obstruction, 6 patients; inguinal hernia, 2; diverticulitis, 2; bowel adenoma, 1; and umbilical, ventral, and hiatal hernias, 1 each.

A pelvic mass found at a routine gynecologic examination led to surgery in six patients. Of the six, only one stage IIIC patient with tumor residual >2 cm died after 7 months' survival. The other five patients are still alive at 35 months (stage IIIA), 35 and 67 months (stage IIIB), and 37 and 89 months (stage IIIC). One patient was diagnosed from a routine Papanicolaou smear that showed adenocarcinoma cells. One patient who did not have a palpable pelvic mass was operated on by urologists for ureteral obstruction.

The characteristics of the seven 5-year survivors are shown in Table VI, which highlights only three long-term survivors with no evidence of disease. Six other patients are alive with no evidence of disease representing stages and residual disease as follows: IIIC, >2 cm (52 months); IIIA, (35 months); IIIB, ≤2 cm (35 months); IIIB, microscopic disease, (29 months); IIIC, ≤2 cm (13 months); and IIIC, microscopic disease (9 months).

A significant relationship between the size of residual tumor and survival rate was demonstrated for patients with stage IIIC platinum-treated disease (Fig. 5). The 5-year/median survival rates for residual disease subgroups were as follows: microscopic disease, 100%/median not yet reached (n = 3); ≤2 cm, 0%/25 months (n = 11); >2 cm, 0%/15 months (n = 26). If only tumor residual ≤2 cm is compared with the subgroup with >2 cm residual, χ^2 is 1.32 yielding $p < 0.3$ and >0.2, which is not significant.

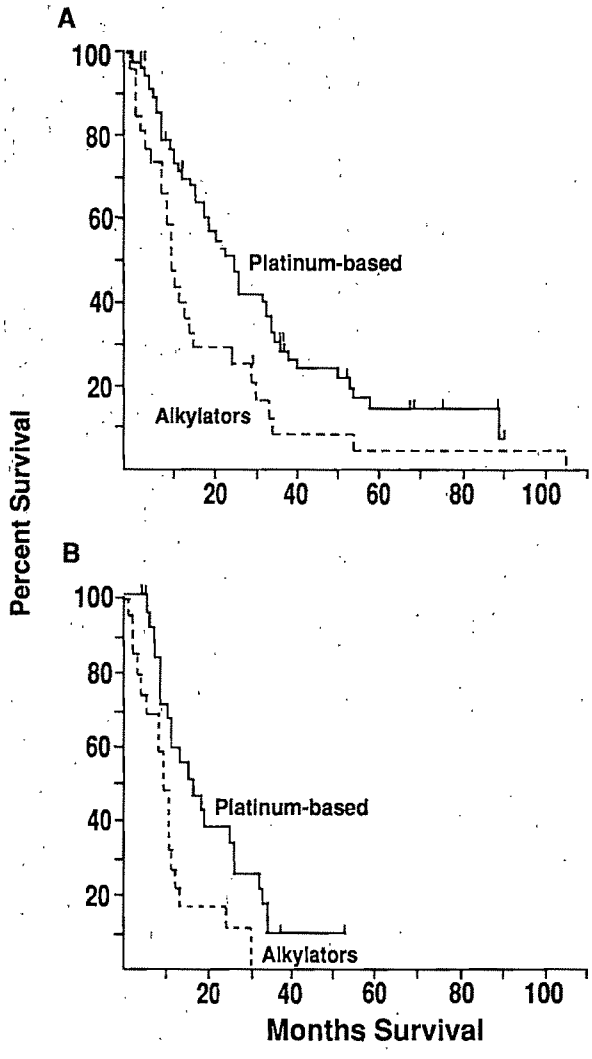

Fig. 4. Survival according to adjuvant chemotherapy **A.** All 86 patients; $\chi^2 = 5.1$; $p < 0.025$ **B.** Patients with stage IIIC disease with >2 cm residual disease; $\chi^2 = 6.3$; $p \simeq 0.01$.

Five patients' tumors were cytoreduced from stage IIIB (n = 2) and IIIC (n = 3) to no visible tumor residual remaining (microscopic). The tumors of 13 stage IIIC patients treated with adjuvant chemotherapy were cytoreduced to ≤2 cm residuum. Table VII indicates that cytoreduction of stage IIIB and IIIC tumor to no visible tumor at the finish of primary surgery results in long-term survival rates comparable with stage IIIA. However, stage IIIC patients with tumors debulked to ≤2 cm were not able to obtain survival curves as good as stage IIIB patients left with visible tumor.

Table IV. Histologic characteristics and tumor grade

Histologic characteristics	*Tumor grade*				
	1	*2*	*3*	*Ungraded*	*Total*
Serous	3	17	17	12	49
Mucinous	0	3	4	5	12
Endometrioid	0	1	5	1	7
Clear cell	1	1	0	1	3
Undifferentiated	0	2	20	6	28
Combination	0	2	0	0	2
TOTAL	4	26	46	25	101

Table V. Presenting symptoms

Symptom	*Number*	*Average duration*
Abdominal		
Pain	58	2½ mo
Distention	48	2 mo
Dyspepsia, nausea, vomiting	15	2 mo
Constipation	10	2½ mo
Diarrhea	6	5 wk
Pelvic		
Pain*	7	2 mo
Urinary difficulty	5	7 wk
Vaginal bleeding	3	2½ mo
Dyspareunia	2	2 mo
General		
Weight loss–gain	18/6	3½ mo
Anorexia	13	5 wk
Fatigue, weakness	11	4 mo

Most patients presented with multiple symptoms.
*Two of these patients also had upper abdominal pain.

Prognosis for a patient who survives primary surgery and is treated with appropriate adjuvant chemotherapy can be obtained from one of three categories based on calculations from this retrospective data. Stage IIIC patients with no visible tumor residual and stages IIIA and IIIB patients had 4- and 5-year survival rates of 67% and 45%, with a median survival rate of 54 months (n = 20); stage IIIC patients with visible tumor residual, had 4- and 5-year survival rates of 8% and 0%, with a median survival rate of 19 months (n = 39); stage IV patients had 4- and 5-year survival rates of 0% and 0%, with a median survival rate of 8 months (n = 8).

Comment

A retrospective chart review of patients with advanced ovarian adenocarcinoma who had primary surgery in a community hospital was done to delineate factors affecting long-term survival. The median age of the patients, 65 years 6 months, suggests that this community-based population could be different from the usually reported university experience. Median ages from comparative studies include 52 years,[10] 53 years,[11] 54 years,[12] and 58 years[13] (the study of Heintz et al.[13] recorded 17% of patients >70 years of age; in my study 36% were >70 years of age). The new FIGO staging classification for stage III disease predicted the subdivisions IIIA and IIIB to have significantly better prognosis than IIIC. The 5-year survival rates for stages IIIA, B, and C of 47%, 29%, and 5%, respectively, are compared with one published standard of 31%, 32%, and 14%, respectively.[14] Confirmation of the terribly poor survival of stage IV cases in spite of adjuvant therapy is the 0% at 5-year and only 8 months' median survival. It is interesting that patients with stage IIIA disease did not have a significantly better overall survival rate than stage IIIB. Incorrect staging affects a study such as this because so many incomplete initial staging procedures were done. The magnitude of this problem has been reported by others.[15-17] For example, in a Gynecologic Oncology Group study of surgical staging, 13 (22%) of 58 patients had the stage of disease elevated at reexploration by a complete surgical-pathologic search.[18] Also, not one of the 71 stage I, II, IIIA, and IIIB charts I reviewed noted retroperitoneal lymph node sampling, which if positive places the patient's disease into stage IIIC. It has been shown that a high percentage of ovarian cancer cases will have retroperitoneal pelvic and periaortic lymph nodes involved with cancer.[19] As shown in a series of 173 stage III cases, lymph node involvement was a negative prognostic factor for survival.[20] The two reasons that have been outlined as the cause for incomplete surgical staging seem applicable to our community.[21] Lack of knowledge about ovarian cancer metastases applies to the cases treated by general surgeons, and lack of surgical expertise pertains to gynecologists technically unable to perform retroperitoneal lymph node biopsies.

The importance of primary surgical cytoreduction in advanced ovarian cancer seems to be established.[22, 23] The findings of my study confirm that cytoreduction at primary surgery can be associated with improved long-term survival. Figs. 2 and 5 show that the larger the tumor residual at primary exploratory laparotomy,

Table VI. Characteristics of seven long-term (5 years) survivors

Months' survival	*Year of surgery*	*Patient status*	*Tumor stage*	*Tumor residual*	*Platinum chemotherapy*	*Histologic characteristics–tumor grade*
105	1974	DOD	III B	≤2 cm	No	Serous-1
90	1983	AWD	III A	Microscopic	Yes	Combination-2
89	1975	DOD	III A	Microscopic	Yes	Serous-1
89	1983	ANED	III C	Microscopic	Yes	Undifferentiated-3
75	1984	AWD	III C	Microscopic	Yes	Serous-3
68	1985	ANED	III A	Microscopic	Yes	Endometrioid-3
67	1985	ANED	III B	≤2 cm	Yes	Endometrioid-2

DOD, Died of disease; *AWD,* alive with disease; *ANED,* alive with no evidence of disease.

Table VII. Survival effect of cytoreduction of stages IIIB and IIIC disease (all patients receiving adjuvant chemotherapy)

Tumor stage	*Tumor residual*	*n*	*Survival rate*		
			5 year (%)	*Median (mo.)*	*p Value*
IIIA	Microscopic	8	47	50	
vs					NS
IIIB and IIIC	Microscopic	5	66	Not reached	
IIIB	≤2 cm	7	33	50	
vs					<0.005
IIIC	≤2 cm	13	0	25	

NS, Not significant.

the poorer the prognosis. Further, it was demonstrated that cytoreduction of stage IIIB and IIIC disease to no visible tumor mass (microscopic disease) resulted in long-term survival rates comparable with stage IIIA (Table VII). When stage IIIB and IIIC tumors could be cytoreduced to microscopic residual, the 5-year survival rates improved to 66% from the respective 29% and 5%. The three patients with stage IIIC disease who had tumors debulked to microscopic residual are still alive at 9 months, 75 months, and 89 months. Table VI demonstrates that the 5-year survivors all had either earlier stage IIIA or IIIB disease or had tumors that were cytoreduced at primary surgery to no visible residual tumor. Stage IIIC patients whose tumors were debulked to ≤2 cm were not able to obtain survival curves as good as stage IIIB patients left with ≤2 cm residuum (Table VII). Also, Fig. 5 reveals that the difference in stage IIIC patients between leaving bulky >2 cm residual disease or debulking to ≤2 cm is minimal and not statistically significant for improved long-term survival. Similar results have been reported indicating that tumor reduction to <2 cm may not be adequate.[10, 24] My study suggests that it is important to achieve as close to no visible tumor as possible at the completion of primary surgery to obtain significant long-term survival benefits. My study was not designed to determine the largest size beyond which benefit is lost. Griffiths suggests it should be at least <1.6 cm.[25] In a recent study, after stepwise combination of categories for an analysis of 268 patients, the best cutoff point for residual tumor size was found to be 1 cm.[26] Gynecologic Oncology Group studies now use the definition of <1 cm as "optimal" debulking.[27] Other studies have not found a magic cutoff that portends a better prognosis, but instead describe decreasing survival in gradual gradations of volume of residual disease.[28] It still seems to be unclear whether the ability to optimally debulk is more from the expertise of the surgeon or at least equally the effect of tumor biology and aggressiveness.[22] Potter et al.[28] found similar survival for patients who required bowel resection and radical techniques to obtain no gross residual disease compared with patients who even had gross residual disease remaining. However, Eisenkop et al.[29] reported at the 1990 annual meeting of the Society of Gynecological Oncologists that patients treated by gynecologic oncologists who debulked tumors to <1 cm residual in 76% of their cases versus 23% for other surgeons had higher survival rates at 3 years.

In spite of impressive initial response in many cases,[30] some recent articles have not demonstrated a clear long-term survival advantage of platinum-based combination chemotherapy over alkylating agents as initial adjuvant treatment of advanced ovarian cancer.[31] In my series survival was better for patients treated with platinum compared with alkylators only in the subgroup

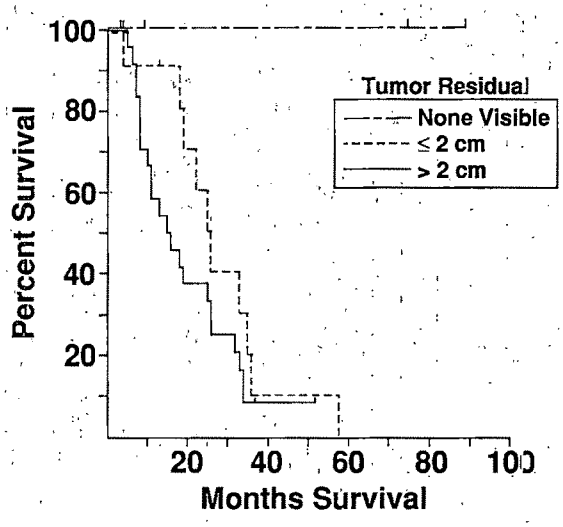

Fig. 5. Survival according to diameter of largest postoperative residual tumor in patients with stage IIIC disease treated with platinum-based combination chemotherapy. Chi-square test for trend yielded 6.2; $p \simeq 0.01$.

of stage IIIC patients with bulky remaining disease. Marsoni et al.[32] analyzed 852 stage III and IV patients from four trial regimens. Platinum-based chemotherapy improved survival rate when residual tumor was >2 cm but not in the subgroup with <2 cm residual tumor size.

Even with advanced adjuvant therapy, I could find no patient who survived to 5 years if there were >2 cm of residual disease after primary surgery. Other authors have reported long-term survivors (>60 months) who had >2 cm residuum. An analysis of 85 stage III and IV patients showed 8 of 20 long-term survivors had >2 cm residual disease after primary surgery.[10] Another noted an 8% 5-year survival rate for the patients who began adjuvant therapy with >2 cm residual disease.[33] As noted in Table VI, three patients are alive with no evidence of disease after 5-year survival. One study with a 10-year follow-up reported 18% 5-year, 11% 7-year, and 7% 10-year survival with no evidence of disease.[11] Another series with long-term follow-up had 18% of advanced ovarian carcinoma patients disease-free from 83 to 118 months after therapy.[12] Two other examples of no evidence of disease 5-year survivors include 13%[10] and 5 (8%) of 62 patients, with 4 having >2 cm disease at the time chemotherapy was initiated.[24]

There continues to be variation among studies as to the prognostic significance of other factors.[26, 34, 35] This study attempted to analyze prognostic factors by the stratification technique of the log-rank method. There was no significant correlation with survival found for age at primary surgery, presence of ascites, histology, grade, parity, speciality of primary surgeons, or prior hysterectomy.

The insidious nature of ovarian cancer results in late diagnosis. Inability to diagnose this disease early is shown by the 65% of epithelial ovarian carcinomas at these two hospitals that were stage III and IV a number that presumably would be even higher if the earlier stages I and II had more complete appropriate initial surgical staging. Moreover, most patients were initially seen with bulky upper abdominal disease; in this study stage IIIC represented 74 of the 101 cases. Symptoms were noted by the patients for an average of 1 to 4 months before the patient had exploratory laparatomy. Because the presenting symptoms were mostly abdominal and not pelvic in nature, 55 of the 101 patients were primarily operated on by nongynecologists. In only 28 cases did a gynecologist and general surgeon combine to complete the surgery. In this community over the period of my study only 23% of stage IIIC tumors were debulked to ≤2 cm diameter of residual tumor nodules. For the last half of my study the figure increased to 32%. Hacker[36] states that 85% of stage III patients' tumors should be debulked to ≤1.5 cm. It has been shown that primary cytoreductive surgery is safe[13, 37] and besides improving survival, does result in increased quality of life.[38] Progress in survival rate was demonstrated for the period 1980 to 1990 compared with 1970 through 1979. For stage IIIC patients this improvement most likely is caused by the increased number of patients whose tumors were cytoreduced (32% compared with 14%) and the value of platinum-based combination chemotherapy in suboptimally debulked tumors. This trend for improvement in survival rate is consistent with national statistics, which show that for all stages and histologic characteristics combined in white women the 5-year survival rate has increased from 36% for the period 1974 through 1976 to 39% during the years 1981 through 1986.[1]

There is no fully effective method of mass screening to detect ovarian cancer in its earlier stages.[39] It should be an achievable goal to diagnose these patients earlier and with more accuracy than is shown in this study. The primary care physician needs to consider the diagnosis in spite of the vague symptoms and quickly seek surgical consultation. Six patients serendipitiously diagnosed by a routine pelvic examination also suggest early diagnosis is beneficial. These asymptomatic patients possibly have improved survival, with only one dying so far; survival in the other five continues at 35 months to 89 months. If the protean symptoms of advanced ovarian cancer can be correctly identified as to source, referral to a gynecologic oncologist seems appropriate. However, if a patient has surgery in a community such as ours, safe tumor debulking may be accomplished by combining a gynecologist with a general-vascular surgeon who is competent operating in the deep vascular area of the pelvic retroperitoneum. This will require educating the medical staff that an aggressive surgical approach is indicated if minimal residual disease will be the result.

Discussion

DR. GLEN E. HAYDEN, Seattle, Washington. Dr. Unzelman, your retrospective study of ovarian adenocarcinoma in two community hospitals involved a monumental task (review of 316 charts) that resulted in the selection of 101 FIGO stage III and IV cases.

As do other studies of ovarian carcinoma, your study shows that age, parity, the presence of ascites, the results of peritoneal cytology, and the tumor grade did not alter the prognosis. Your finding that 65% of the patients were in disease stage III and IV is in accord

with most studies, and your findings in regard to ultimate outcome closely match the results at major centers. The results of 1980 and 1990 show an improved prognosis with prolonged life expectancy. This study should result in better staging and initial debulking of advanced ovarian lesions at your hospital in the future. It is good that you point out the need for node sampling in stage III cases. A second factor in the improved survival rate was the recent addition of more effective chemotherapeutic agents, especially cisplatin and carboplatin. The immediate postoperative mortality rate of 5% is relatively high, but may reflect the older age of this group (median age 65 years).

This presentation clearly points out the need for early diagnosis. Family history cannot clearly identify the high-risk patient unless a first-order relative is involved, such as a mother or a sister. Yearly pelvic examination and pursuit of all adnexal masses are the foundation of good management. Additional tools now available are CA 125, ultrasonography, and laparoscopy. In their recent review of screening for ovarian cancer with CA 125 and ultrasonography Creasman and Disaia[1] agreed with the American College of Obstetrics and Gynecology committee opinion that these techniques are not suitable for routine screening.

The use of oral contraceptives definitely reduces the incidence of ovarian cancer by 50%. I believe that patients recognizable as being at high risk for ovarian cancer should be placed on oral contraceptives and continued on them regardless of age as long as they remain nonsmokers.

DR. MICHAEL SMITH, Seattle, Washington. Two years ago I reported our experience with aggressive intestinal resection as part of the initial debulking of ovarian cancer.[1] At that time I was asked whether there was a survival advantage to such aggressive surgery. I was unable to answer the question, but I did feel that the quality of life was improved by reducing the need for subsequent colostomy or other intestinal surgery. I can now report that studies from Duke[2] and Alabama[3] have answered that question. Both reported no survival advantage. I fully agree with Dr. Unzelman concerning the need for complete primary debulking, but not to the extremes formerly recommended. I think that the data will also fail to show a survival advantage for patients who have undergone cavitron ultrasonic aspiration or argon-beam coagulation of difficult-to-resect diaphragmatic or mesenteric disease. Progress in this disease will come from advances both in early detection and in chemotherapy rather than from more aggressive surgery.

DR. WILLIAM LUCAS, Ashland, Oregon. For the two and one-half decades before last year I was very involved with aggressive surgical attacks on ovarian cancer. During the last year I have had time to reflect on this surgical approach to ovarian cancer. I draw a different, and somewhat heretical, conclusion from the data Dr. Unzelman presented. It is far from proved that an aggressive surgical attack on ovarian cancer is always a valid approach to the treatment of this disease. It is primarily the intrinsic biologic characteristics of the tumor, including whether it is sensitive to chemotherapy, that determine the long-term prognosis. An aggressive initial attack is well validated. However, let me remind you that there are groups such as the West Midland Ovarian Cancer Group in England that have good data to show that an aggressive primary chemotherapeutic attack works almost as well, if not just as well, as an aggressive primary surgical attack, and that second-look surgery does not improve survival.[1] I am disturbed by aggressive secondary and tertiary surgery for ovarian cancer. Almost by definition, the patients subjected to secondary or tertiary debulking are those who have failed aggressive chemotherapy. Their tumors are not going to have a good response to surgery except in the very short term. In my view we are subjecting patients to a lot of morbidity, physical and psychologic, at great cost for questionable benefits.

DR. ENRIQUE C.M. DECASTRO, Portland, Oregon. Dr. Hayden says that ultrasonography is too costly to be done on a routine basis; I am concerned because early detection of ovarian cancer should be our goal. Pelvic ultrasonography allows us to evaluate the pelvic cavity with greater certainty than bimanual examination alone.

Brachial plexus palsy: An old problem revisited

Raymond J. Jennett, MD,[a] Theodore J. Tarby, MD,[b] and Carol J. Kreinick, MA[c]
Phoenix, Arizona

OBJECTIVES: It is an almost universal assumption in obstetric literature that brachial palsy is due to extreme lateral traction on the fetal head during the last phase of delivery. In contrast, there have been reports in the neurologic literature of probable intrauterine origin of brachial plexus palsy. Data to dispute or support the latter view were sought.
STUDY DESIGN: With this overview in mind, our perinatal data base was searched for all instances of shoulder dystocia and independently for all diagnoses of brachial plexus impairment.
RESULTS: Seventeen instances of brachial plexus impairment associated with shoulder dystocia were found. Twenty-two instances of brachial plexus impairment without mention of shoulder dystocia were ascertained. The characteristics of the two groups were remarkably different, especially in birth weight and in maternal age and parity.
CONCLUSIONS: The data are strongly suggestive that intrauterine maladaptation may play a role in brachial plexus impairment. Brachial plexus impairment should not be taken as prima facie evidence of birth process injury. (AM J OBSTET GYNECOL 1992;166:673-7.)

Key words: Brachial plexus impairment, shoulder dystocia, intrauterine maladaptation, medicolegal implications

Brachial plexus impairment appears to be a frequent and increasing reason for the instigation of medicolegal action. In a 5-year period in one hospital it was the reason for seven of 103 (6.8%) obstetrics-gynecology related lawsuits.[1] Indeed, some authors[2] stated that it was highly probable that in the future all cases of shoulder dystocia with a suboptimal outcome would be litigated. It is accepted by these and others that the injury always results from extreme lateral traction on the head during delivery of the shoulders. Since plaintiff's attorneys adduce evidence that the risk of shoulder dystocia is predictable and therefore brachial plexus damage is preventable, increasing attention is being given to this aspect of the problem.

On the other hand, little attention has been given to the possibility that brachial plexus impairments occur without evidence of birth trauma, just as do other nerve impairments such as facial palsy, isolated phrenic nerve impairment, and radial nerve palsy.[3-5] Furthermore, neurologic literature contains descriptions of brachial plexus impairments that were almost certainly of intrauterine onset.[6,7] Major evidence for intrauterine onset was based on electromyography. It takes approximately 10 days for muscle to develop electromyographic evidence of denervation; therefore such findings in the early neonatal period support an intrauterine onset of the impairment.

These observations led us to analyze our perinatal data base for data to either support or argue against the proposition that brachial plexus impairment may be caused by factors other than force occurring with delivery of the fetal shoulders.

Material and methods

The perinatal data system for our hospital has been previously described.[8] Data for 57,597 births occurring from 1977 through 1990 were analyzed for distribution by maternal age and parity, delivery mode, gestational age and birth weight, Apgar scores, and need for admission to the intensive care nursery. Separate searches for all recorded diagnoses of shoulder dystocia and brachial plexus impairments were conducted. If other peripheral nerve damage had occurred in conjunction with brachial plexus impairment, these were ascertained, but no separate search for other peripheral nerve damage or skeletal trauma was carried out.

Results

Thirty-nine infants were diagnosed as having incurred brachial plexus impairment. The impairment ranged from weakness of an upper extremity in three infants to a specific diagnosis of brachial (Erb's) palsy in the other 36. No diagnoses of lower plexus (Klumpke's) palsy were recorded. Seventeen of the brachial plexus impairments were associated with a recorded diagnosis of shoulder dystocia whereas 22 had

Second stage >1 hr	9/17	53	7/22	32

no such association. The contrasting characteristics of the two groups were analyzed and are presented in a series of tables. In the appropriate tables "with specific diagnosis" indicates the group for which this diagnosis was recorded and "without specific diagnosis" indicates that this diagnosis was not recorded for this group.

The contrasting maternal characteristics are shown in Table I. Approximately a third of the mothers in the group with no recorded shoulder dystocia were <20 years old whereas only one of the 17 with shoulder dystocia was in this age group ($\chi^2 = 4.496$, $df = 1$, $p < 0.05$). The contrast in parity was even sharper. Sixty-four percent of the non-shoulder-dystocia group were primigravid compared with 29% of the shoulder-dystocia group ($\chi^2 = 3.956$, $df = 1$, $p < 0.05$).

Labor and delivery variations are listed in Table II. Spontaneous vaginal delivery was more than twice as common in the non-shoulder-dystocia group with slightly more than half of these infants being delivered in that manner. These differences, although clinically impressive, were not statistically significant ($\chi^2 = 1.303$, $df = 1$). Vaginal breech delivery accounted for two of the brachial palsies in the non-shoulder-dystocia group. One infant at 30 weeks' gestational age was delivered as a frank breech and weighed 1786 gm. The other, a compound breech, was delivered at 34 weeks and weighed 2934 gm. One infant in this group was delivered by cesarean section without mention of any delivery problem, including delivery of the shoulder. The 41-week infant weighed 2572 gm. The infant was in a transverse lie presentation with the umbilical cord around the neck two times. Although a second stage >1 hour was only slightly more common in the shoulder-dystocia group, this was probably made more significant by the fact that only 29% of nulliparous women were in this group as compared with 24% in the non-shoulder-dystocia group.

Table III. Brachial plexus impairment with and without mention of shoulder dystocia

2501-3500 gm	1/17	6	10/22	46
3501-4000 gm	4/17	24	4/22	18
4001-4500 gm	7/17	41	2/22	9
>4500 gm	5/17	29	3/22	13

*Infant of diabetic mother born at 34 weeks and weighing 4253 gm.

Contrasts in infant characteristics are shown in Table III. Five of the 22 infants in the non-shoulder-dystocia group were <36 weeks as compared with only one in the shoulder-dystocia group ($\chi^2 = 2.090$, $df = 1$, NS). The only preterm infant in the shoulder-dystocia group was born to a diabetic mother at 34 weeks and weighed 4253 gm. The five preterm infants in the non-shoulder-dystocia group were born at 30, 31, 33, 34, and 34 weeks. On the other hand, 41% of the shoulder-dystocia group were >40 weeks' gestation as compared with only 14% of the non-shoulder-dystocia group ($\chi^2 = 3.815$, $df = 1$, $0.10 > p > 0.05$).

Contrasts in birth weight were more impressive (Table III and Fig. 1). Thirteen of the 22 infants (60%) of the non-shoulder-dystocia group weighed <3500 gm as compared with only one in the other group. Twelve of 17 (70%) in the shoulder-dystocia group weighed >4000 gm as compared with 5 of 22 (44%) is the non-shoulder-dystocia group ($\chi^2 = 13.138$, $df = 3$, $p < 0.01$). It is of interest that the largest baby, who weighed 5727 gm and was delivered spontaneously, was not recorded as having shoulder dystocia.

Certain aspects of birth condition are listed in Table IV. Sixty-five percent of the shoulder-dystocia group had a 1-minute score of <7 compared with 36% of the non-shoulder-dystocia group ($\chi^2 = 3.083$ $df = 1$, $0.10 > p > 0.05$). At 5 minutes 41% of the shoulder-

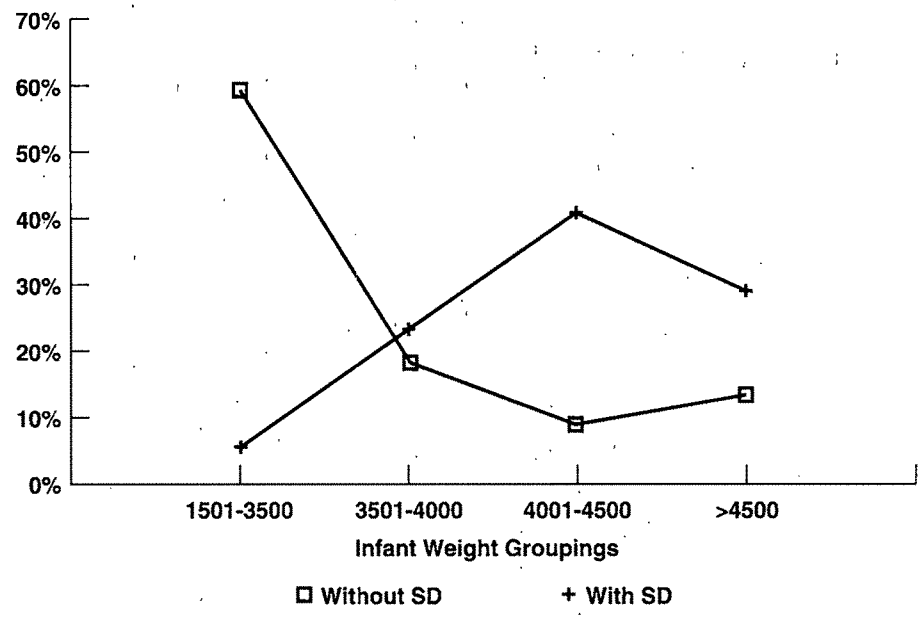

Fig. 1. Weight groupings by percentage of infants with brachial palsy with and without associated diagnosis of shoulder dystocia *(SD)*.

dystocia group had a score of <8 compared with 14% of the non-shoulder-dystocia group ($\chi^2 = 3.815$, $df = 1, 0.10 > p > 0.05$). These differences are suggestive but not statistically significant.

The only associated nerve involvements occurred in the non-shoulder-dystocia group. No clavicular fractures were recorded in either group. However, one infant in the non-shoulder-dystocia group who was delivered spontaneously after a 36-minute second stage had bilateral femoral fractures, as well as bilateral brachial plexus palsy. Gestational age was 37 weeks and birth weight was 2586 gm.

The question of possible underrecording of shoulder dystocia is a legitimate one, and the incidence of shoulder dystocia with associated brachial plexus impairment by year and by weight groupings was analyzed and is displayed in Table V.

Comment

As reflected in the title of this article the focus is on brachial plexus impairment and only secondarily on shoulder dystocia. The term *brachial plexus impairment* rather than *brachial plexus injury* was used advisedly, inasmuch as the latter term carries with it the connotation that direct physical trauma is always involved.

In this large group of patients whose infants were delivered over a 13-year period, 22 of 39 (56%) cases of brachial plexus impairment were not associated with recognition of difficulty with delivery. Indeed, one was associated with cesarean section. Gonik et al.[9] made the same observation in a smaller group of patients in which 71% of infants with shoulder girdle impairment did not have shoulder dystocia recognized in the delivery process. Those authors attributed this lack of recognition to more subtle instances of shoulder dystocia without clinician recognition of the problem.

We concede that a lack of recognition of shoulder delivery problems may be involved in some of the brachial plexus impairments in this group. However, the contrasting characteristics strongly suggest that other factors are involved. The differences in maternal age and parity are significant. If the impairments were associated only with subtle, unrecognized shoulder dystocia, it would be expected that age and parity would be similar in the two groups. Actually, maternal age <20 was five times greater in the non-shoulder-dystocia group and nulliparity was more than twice as common.

Table V. Shoulder dystocia and associated brachial plexus impairment by year

*Percent of infants with shoulder dystocia and brachial plexus impairment.

It has been postulated that intrauterine pressures associated with uterine anomalies could be a factor[5] Although the presence of such anomalies could not be determined from the available data, uterine maladaptation associated with young maternal age and nulliparity might well be associated with a higher incidence of intrauterine pressures resulting in nerve impairment. Spontaneous vaginal delivery was more than twice as common in the non-shoulder-dystocia group, suggesting less probability of difficulty in delivery. Certainly, the brachial plexus impairment in a 2572 gm infant delivered by cesarean section from a transverse lie would have a high probability of intrauterine maladaptation as a cause.

The increasing incidence of diagnosed shoulder dystocia during the period of this study without an increase in associated brachial plexus impairment deserves comment. Rather than an underrecording of shoulder dystocia, it would speak to an increasing awareness of the medicolegal implications of the condition and a tendency to record even minor degrees of difficulty. This in turn would make subtle, unrecognized shoulder dystocia a less likely cause of brachial plexus impairment.

Weight distribution is another significant factor. Almost 60% of the infants in the non-shoulder-dystocia group weighed <3500 gm with approximately one third weighing <3000 gm. The probability of unrecognized problems in this weight group is low. On the other hand, the possibility of a uterine maladaptation problem could exist as well with the larger infant. The occurrence of brachial plexus impairment in five preterm infants is inconsistent with shoulder dystocia inasmuch as shoulder circumference is almost always less than head circumference.

The occurrence of more instances of brachial plexus impairment without recognizable problems with the delivery of the shoulder than when such a problem is perceived renders basically untenable an argument that brachial plexus and other related nerve impairments are predictable. Nor can brachial plexus impairment with diagnosed shoulder dystocia be taken as prima facie evidence that the two are causally related in all such instances.

The role of electromyography in identifying possible onset of brachial plexus palsy during the antenatal period as suggested by Koenigsberger[6] was not addressed during this study but will be the focus of an anticipated subsequent report.

Discussion

DR. CARL GOETSCH, Berkeley, California. Dr. Jennett and colleagues have made a significant contribution to the growing evidence that not all untoward outcomes of delivery are caused by events during the process of labor and delivery. They have shown that such outcomes may, in fact, result from conditions that antedate delivery or even labor. This article clearly shows that although impaired function of the brachial plexus may have been associated with shoulder dystocia (46%), an even larger group (54%) had no dystocia. In fact, one case was delivered by cesarean section. Dr. Jennett listed findings that differentiate the two groups and cited the reports from as early as 1956 by pediatricians and neurologists who pioneered in studies of this problem.

In spite of its limits, this report is important because it enlarges the literature on the problems of development and function encountered in both the gestational and parturitional phases of our arrival on this troubled planet. A partial solution to one problem that plagues

the obstetrician, the threat of professional liability, is expansion of our knowledge of the causes of these dysfunctions. With this knowledge, the expert witness increases his competence, the defense attorney is armed, and the plaintiff's attorney is, to the same degree, disarmed.

Dr. Jennett, in his discussion, points out the desirability of using the term *brachial plexus impairment* instead of the term *injury*, which offers the opposing attorney the opportunity to argue that the physician caused the injury. I add as alternatives *dysfunction* or the old term *palsy*. Good defensive record keeping requires cultivating our sensitivity to the semantic implications of the words we use.

Dr. Jennett promises to continue to study other aspects of brachial plexus palsy, especially the use of electromyography as a diagnostic tool. Considering the low incidence of brachial plexus palsy, that is a formidable task. I congratulate Dr. Jennett and his team for their imaginative extraction of the "gold" sequestered in their computer data bank in Phoenix.

Dr. Julian T. Parer, San Francisco, California. It is my impression that many plaintiff's lawyers are reluctant to press shoulder dystocia cases because it is clear that prediction of shoulder dystocia is extremely difficult. It is also difficult to show that the physician delivering the infant did not go through all the appropriate steps. It is interesting to read depositions by the defendant obstetricians because they almost cite chapter and verse out of *Williams' Obstetrics* in describing exactly what they did.

With regard to the method of delivery after shoulder dystocia is recognized, I was taught to avoid putting heavy traction on the anterior shoulder and, if other appropriate steps do not work, to deliver the posterior arm by the strenuous technique of forcing my hand up posteriorly to grasp the forearm. Can you tell us about the method of delivery used for the infants who had shoulder dystocia?

Dr. Lester T. Hibbard, Carmel, California. Did all these infants have a permanent injury or did some have a temporary injury?

Dr. James D. Fearl, Portland, Oregon. In how many of these cases of shoulder dystocia was the impairment identified by the obstetrician after delivery? I think that today there is a tendency for obstetricians not to carefully evaluate healthy-appearing babies. You will have better rapport with your patient if you yourself identify the impairment, rather than being called later by the nursery or, even worse, being told by the mother when you return on postpartum rounds.

Dr. Philip E. Young, San Diego, California. I disagree with Dr. Parer and believe that shoulder dystocia malpractice cases will be increasingly common. I have appeared as an expert witness for the defense in five cases of shoulder dystocia and brachial plexus palsy. The defense prevailed in each. In one, the judge threw the verdict for the defense, citing from *Williams' Obstetrics* the comment to the effect that care must be taken not to apply excess lateral traction because such application may cause a brachial plexus injury. This statement was interpreted by the judge to mean that this is *the* way the injury occurs in cases of shoulder dystocia, not just *a* way.

Dr. Jennett pointed out that at least half of these brachial plexus impairments may not be related to shoulder dystocia at all. I would say further that even when the impairment is associated with shoulder dystocia, it may be quite independent of any lateral traction applied by the obstetrician. I was once present at a delivery in the emergency room. My partner, having been called in to see a very large lady with no prenatal care who was just about to deliver, called me in because he thought he might encounter shoulder dystocia. The patient was pushing, but neither of us was prepared to do anything that instant because we were still gowning. Out came the head and immediately it retracted back. Every medical person in the room recognized this as an obvious case of shoulder dystocia. Then the woman yelled and pushed again. The baby went sailing and was just barely caught by my partner. The infant, untouched by human hands until after it was delivered, had brachial plexus palsy. I believe that the mechanism of injury in this case was the shoulder dystocia itself. The baby had a large stubby neck and the mother's obesity made her birth canal effectively much longer. For some patients shoulder dystocia and brachial palsy are indeed associated, but the association is not that the obstetrician placed traction on the head. The association is that the forces of labor and delivery place traction on the plexus.

If the members of this society who write obstetrics textbooks would see that this information provided by Dr. Jennett is promulgated, it would be a big help to practicing obstetricians.

Dr. Jennett (Closing). Dr. Parer, the methods used to deal with shoulder dystocia are not recorded in the computerized record. An analysis of that question would require a search of each microfiche record, and we did not do this because brachial plexus impairment was our focus. We did determine whether the delivery was done by a resident or by a member of the attending staff. Twenty-five percent were done by the residents and 75% were done by the attending staff. In our hospital 25% of the patients are cared for by the residents and 75% by the attending staff. This led us to believe that in this situation experience does not have much to do with the outcome.

Dr. Hibbard, the impairment was temporary. Dr. Tarby, our pediatric neurologist who examined most of the infants with brachial plexus impairment born during the last 7 years, does not recall any who had a permanent impairment.

Dr. Fearl, I think that often the obstetrician did not known that the infant had incurred a brachial plexus palsy. The obstetrician who delivered one baby who had bilateral brachial plexus palsy recently told me that, although it was an important subject, he himself had never delivered a baby with brachial palsy.

Modified retropubic cystourethropexy II

John A. Goodno, Jr., MD, and Thomas W. Powers, MD
Arcadia, California

In 1986 we published a preliminary report describing a modification for bladder-neck suspension in the treatment of urinary stress incontinence. From 1982 through 1989 135 surgical procedures were performed. Long-term follow-up of these patients is now presented. Of the 135 patients in this study, 118 were available for follow-up at the time of this report; 108 (91.5%) of the 118 reported no urinary leakage. Of the 10 patients who reported continued urinary leakage, only 2 had persistent or recurrent urinary stress incontinence; they were reoperated on with favorable results. The other eight patients reporting urinary leakage were patients with mixed-cause urgency incontinence. The adjusted success rate for the treatment of genuine stress incontinence was therefore 98%. (Am J Obstet Gynecol 1992;166:1678-82.)

Key words: Urinary stress incontinence, urgency incontinence, modified retropubic cystourethropexy

As more women look to the gynecologist as their primary care physician, the gynecologist is confronted with an increasing number of women who have urinary incontinence. It is anticipated that as women live longer into the postmenopausal years the incidence of urinary incontinence will increase. Brockelhurst et al.[2] found that 57% of women ages 45 to 64 years in a general practice population had stress incontinence. Norton[3] pointed out that some patients assume that the problem is normal and do not seek medical advice; therefore the physician must carefully question patients about their urinary function.

The literature is replete with articles on the subject of urinary stress incontinence, with over 100 procedures described.[4] Physicians must choose the appropriate surgery for each individual on the basis of careful study of the patient's pathophysiologic findings.

Our original publication reviewed the short-term results of 26 patients who underwent modified retropubic cystourethropexy between December 1982 and April 1985.

Our present study is an ongoing analysis of this procedure, which was further modified in 1987 by substituting cystotomy with suprapubic telescopy.

Material and methods

Operative technique. All patients were given a preoperative antibiotic, usually a second-generation cephalosporin, intravenously just before surgery. At the time of surgery the pelvic examination was repeated with the patient under anesthesia, and urethral dilatation was performed if indicated. The patient was placed in the "frog-leg" position and the abdomen, vagina, vulva, and inner thigh areas were prepared and draped in a sterile manner. A transurethral Foley catheter was inserted into the bladder and its balloon inflated with 5 to 10 ml of water. A Y connector was attached to the catheter so that both bladder drainage and filling could be accomplished as required.

The procedure was usually performed through a transverse suprapubic incision. In obese patients or patients in whom added exposure was necessary, a Maylard muscle-splitting incision was used. Hysterectomy or other indicated intraperitoneal procedures were performed, and the peritoneum closed before the retropubic space was entered. The paraurethral fatty tissue was carefully dissected away, and a Babcock clamp was placed around the urethra just below the ureterovesical junction. With two fingers in the vagina as a guide, a No. 1 Novafil suture was placed in the vesicovaginal fascia on each side of the bladder neck approximately at right angles to the urethra, with a helical technique (Fig. 1).

Indigo carmine dye was given intravenously, and the bladder was retrofilled with 400 ml of water. A size 00 chromic purse-string suture was placed in the dome of the bladder, and a needle-tip cautery was used to create a small cystotomy within the sutured area. The telescope of the cystoscope (without its sheath) was inserted into the bladder through this cystotomy, and the bladder was inspected for inadvertent suture penetration. The ureteral orifices were visualized until blue-dyed urine was spurting from each side. The telescope was withdrawn, and a No. 14 silicone elastomere Foley catheter placed through the same cystotomy incision; the catheter balloon was inflated and the purse-string su-

6/6/37488

ture securely tied around it. The catheter exited the abdomen through a stab incision just inferior to the suprapubic incision in the right lower quadrant. The retropubic space was drained with a No. 10 Jackson-Pratt suction drain (Heyer-Schulte, Irvine, Calif.) exiting through a stab incision in the left lower quadrant of the abdominal wall.

The swaged needles of the Novafil suspensory sutures were cut, and the two ends of one suture were threaded onto a free Mayo needle; the needle was passed through the inferior aspect of the muscle and fascia just above the symphysis pubis 1 to 2 cm lateral to the midline. The same procedure was repeated on the opposite side.

After closure of the rectus fascia the two suspensory sutures were tied to each other across the inferior aspect of the rectus fascia so as to elevate the bladder neck. The degree of elevation of the bladder neck was determined with a small urethral dilator or cotton-tip applicator placed into the urethra; the urethral axis was estimated while the suspensory sutures were tied down (Fig. 2). A urethral axis of 10 to 20 degrees below the horizontal was considered optimal for this suspension procedure.

Postoperatively, the suprapubic catheter was connected to gravity drainage for the first 24 hours. On the second postoperative day the catheter was plugged, and the patient was allowed to void or to attempt to void. The residual urine was measured after each voiding. When voiding was adequate (that is, a urine residual consistently <100 ml) the catheter was removed. Patients were usually discharged on the third or fourth postoperative day with or without the suprapubic catheter. If they were not yet voiding adequately, they were instructed to call the office when they were able to void without significant residuals. Those patients discharged with their suprapubic catheters were given prophylactic antibiotics, such as Bactrim DS. More recently, in selected patients in whom only cystourethropexy was performed the procedure has been done on an outpatient basis and the patient has been discharged the same day.

Evaluation and patient characteristics. The procedure was performed on 135 patients between December 1982 and December 1989. The two authors and an associate performed all of the surgeries. Patient evaluation before surgery was detailed in our previous publication.[1] We usually used a simplified urogynecologic work-up as described in a recent publication of the American Uro-Gynecological Society.[5]

Forty-seven (34.8%) patients had preoperative urethrocystoscopy and cystometry. Two patients had multichannel urodynamic assessments. Patients who had urinary stress incontinence but who exhibited genital prolapse were operated on transvaginally; indicated surgery was performed together with a modified Per-

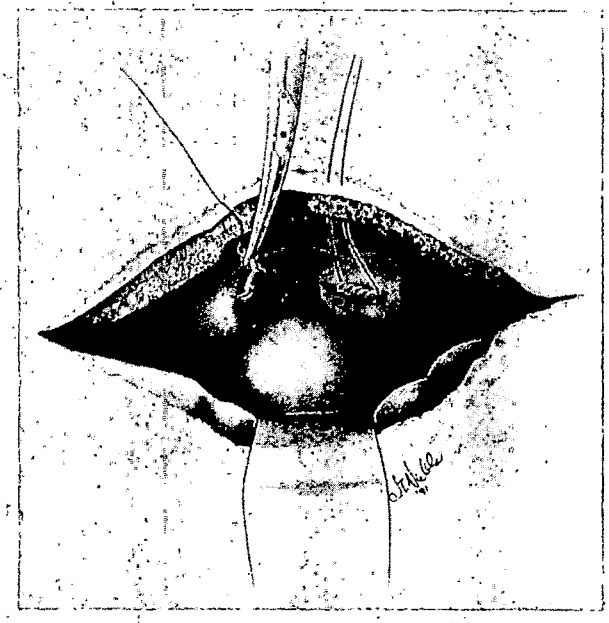

Fig. 1. Helical suture in paraurethral fascia.

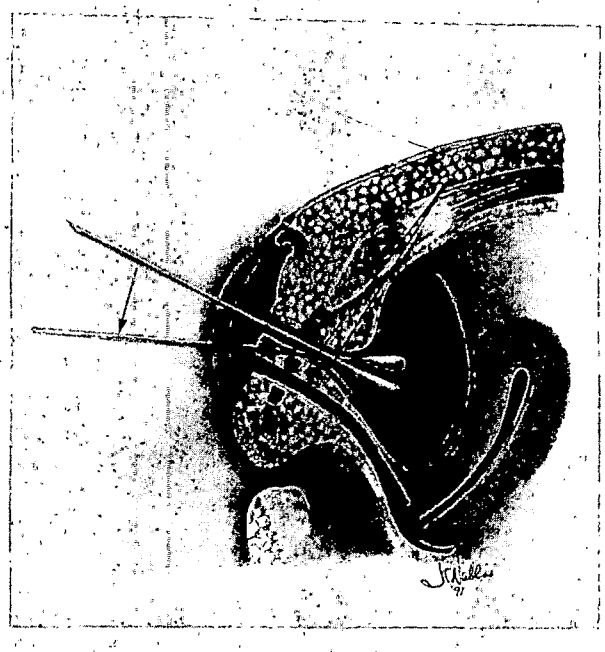

Fig. 2. Cotton-tip applicator in urethra as guide to change in urethral axis with tying down of suspensory suture.

eyra suspension of the vesical neck. Our article deals only with those patients who had a transabdominal retropubic procedure.

Forty (29.6%) patients underwent modified retropubic cystourethropexy only; 95 (70.3%) had additional surgery such as hysterectomy or salpingooophorectomy. Patients ranged in age from 27 to 72 years; 47 (34.8%) patients were >50 years of age. Postoperative follow-up time for the patients in this study was from

Table I. Overall results

1 to 8 years. Seventy (51.8%) patients have been monitored for ≥4 years since their surgery.

Results were assessed by physical examination and each patient's subjective report of her urinary status. Objective testing, including urodynamic studies, was not routinely performed postoperatively in this clinical study.

Results

All charts were reviewed and patients were contacted by telephone in January 1991. Two patients had died, and 15 had either moved from the area or were lost to follow-up. One hundred eighteen patients were available for follow-up. One hundred eight (91.5%) patients reported that they did not experience any urinary leakage (Table I). Ten patients continued to have urinary leakage after surgery (Table II). Eight of these patients had persistent urgency incontinence. All but one of these eight patients had preoperative urethrocystoscopy and cystometric studies and were diagnosed as having mixed-cause incontinence (i.e., anatomic incontinence and detrusor instability) preoperatively.

Of the two patients whose surgeries were classified as failures to correct anatomic stress incontinence, one patient noted recurrent stress incontinence 2 years postoperatively and was reoperated on by us in 1987. At her interview in January 1991 she reported that she was dry. The other patient who did not experience relief in her urinary incontinence had received pelvic radiation for adenocarcinoma of the endometrium 2 years before her retropubic cystourethropexy. In addition, she had been classified as having mixed-cause incontinence after her preoperative urethrocystoscopy and cystometric study.

Of interest is the fact that 2 years after an unsuccessful outcome with our procedure, a Raz procedure[6] was performed; the patient reports considerable improvement, although she is not completely dry. Excluding the eight patients with mixed-cause incontinence who continued to experience urgency incontinence, the adjusted success rate in anatomic urinary stress incontinence for this procedure was 98.3%.

Comment

The basic principles in our surgical modification are (1) the use of a helical, nonabsorbable suture in the paraurethral fascia, (2) a suprapubic cystoscopy to rule out inadvertant urinary injury, (3) the use of a cotton-tip applicator or urethral dilator in the urethra to gauge the urethral axis and prevent possible overcorrection, and (4) the fixation of the suspensory suture to the anterior rectus fascia just above the symphysis pubis.

The advantage of the helical suture is that it produces a thickening and pleating of the paraurethral tissues to prevent the suspensory suture from pulling out of the tissue; this advantage has been described by Pereyra and Lebherz.[7]

With the use of permanent suture the possibility of inadvertent bladder penetration must be considered; when performing suprapubic cystoscopy we have observed on occasion a pass of the Novafil suture in the bladder and have simply removed and repositioned the suture without any subsequent problem. We have observed no fistulas or permanent urinary injuries in any patients.

With any type of cystourethropexy to correct anatomic urinary stress incontinence, the possibility of overcorrection of the urethral axis exists. Overcorrection may result in obstruction with large postvoid residuals and inefficient voiding with bladder instability, frequency, and urgency.[8] By using an object in the urethra to gauge the urethral axis while tying down the suspensory suture, there is less chance of overcorrection. We have occasionally seen transient high postoperative urinary residuals requiring urethral dilations, but no patients have had permanent voiding dysfunction or required takedown of the repair.

The use of the anterior rectus fascia to anchor the suspensory suture proved quite effective; in the one failure that was reoperated on by us the suspensory suture had pulled out of the paraurethral fascia, but the suture in the rectus fascia was intact.

Although the modified retropubic cystourethropexy is more time-consuming than the needle-suspension procedures,[9] results appear to be superior to these procedures and appear to be comparable to the Burch procedure.[10]

The follow-up time in this study (1 to 8 years) is of relatively short duration to provide objective criteria for judging this procedure's effectiveness; as is pointed out by Benson et al.,[11] a 5- to 10-year follow-up period is required to properly evaluate any antiincontinence procedure. Further underscoring the need for long-term follow-up, Stanton[12] reported a 94% cure rate for the Burch procedure at 1 postoperative year and 77% at 5 postoperative years.

The failure of this procedure to correct the urgency component of incontinence in the 8 patients with

mixed-cause incontinence points up the need to carefully review and discuss the possibility that surgery may not result in these patients being totally dry postoperatively.

Whether antiincontinence surgeries should be performed in patients with mixed-cause incontinence has been controversial. Stanton[12] has suggested that the degree of rise in detrusor pressure on cystometric evaluation of those patients with detrusor instability may be an important predictive observation of potential failure. According to Kohorn,[13] in patients with mixed-cause incontinence, the less severe the anatomic defect the more likely it is that the associated detrusor instability will subside after bladder-neck suspension surgeries.

An excellent study by Ramon et al.[14] concluded that a good anatomic repair was the most important factor in the management of incontinent patients who exhibit hypermobility of the bladder neck regardless of the coexistence of urethral weakness or detrusor instability.

As we continue to use our modification of the retropubic cystourethropexy we are encouraged by its relative simplicity and lack of postoperative voiding problems. The 98% clinical cure rate for genuine stress incontinence over the 1- to 8-year observation period in this series is encouraging, and we feel that this procedure belongs in the repertoire of the urogynecologist.

Discussion

Dr. David Pent, Paradise Valley, Arizona. This is a welcome follow-up report on a surgical technique that Dr. Goodno first reported to this Society 6 years ago. At that time his series consisted of 26 patients monitored for 10 months to 4 years. Now he presents five times as many patients with a follow-up period of 1 to 7 years, with the majority having been operated on ≥4 years ago.

Regarding Dr. Goodno's reported cure rate, these figures are based on information reported by the patient in a telephone interview. Because the International Continence Society definition of incontinence involves it being a social and hygeinic problem, it seems appropriate to consider the patient cured on the basis of her statement that her incontinence is no longer a problem. However, some patients' replies might be influenced by wanting to please the doctor or by fear of having to undergo a repeat surgery, so an objective measurement of incontinence, such as a perineal pad–weighing test, would seem to be of value and would help in comparing these results with those of other authors.

Most of Dr. Goodno's surgical failures involved patients who exhibited mixed incontinence—both genuine stress incontinence and detrusor instability—on preoperative testing. I wonder whether these patients were tested postoperatively to confirm that their persistent incontinence was caused by the detrusor instability, because symptoms alone can be very misleading. I am a little disturbed over dropping these uncured mixed-cause incontinence patients from the calculation of the stress incontinence success rate because those patients with mixed incontinence who were cured were counted. I think it would be better to treat these as two separate groups and report a success rate for each. This would also help shed some light on the role of surgery in the presence of mixed incontinence which, as Dr. Goodno notes, is controversial to say the least. In any event his success rate of 108 patients in the 118 on whom follow-up could be obtained is excellent and is comparable to the Burch procedure.

Dr. Goodno notes that many women with incontinence do not seek medical advice, and I believe that there are two main reasons. First, as he notes in quoting

Norton, many women feel that this is a normal part of aging. Indeed, this is an essential part of the individual's coping mechanism—it is easier to cope with a "normal" process than to deal with an illness. And the fact that June Allyson talks about Depend undergarments on television and that supermarket shelves are stocked with protection apparel only serves to reinforce the idea that incontinence with aging is normal.

Second, many patients are afraid to discuss their incontinence problems because they assume surgery will be necessary. We need to make women aware that nonsurgical modalities can help. The use of biofeedback, physiotherapy, weighted vaginal cones, and electric stimulation have enhanced the effectiveness of pelvic-floor–muscle exercises and have demonstrated a high degree of success. In the past many gynecologists have been disappointed in the results of the Kegel exercises, but numerous studies have shown that most patients who believed they were doing Kegel exercises were really doing nothing more than contracting abdominal and gluteal muscles and not their perineal musculature.

Dr. Goodno's cystourethropexy procedure is relatively simple to perform; his excellent cure rate, along with the lack of postoperative voiding problems, recommends this technique to any surgeon dealing with urogynecology. As he has noted, long-term follow-up is essential, and I look forward to hearing a further update of the results in another 5 to 6 years.

DR. HOWARD BLANCHETT, Berkeley, California. Do you think that as we approach the 21st century there will be a declining incidence of stress incontinence because of declining parity, declining operative vaginal deliveries, and increasing emphasis on women's physical fitness?

DR. GOODNO (Closing). Dr. Pent, you brought up the important issue of the nonsurgical management of the incontinent patient, including pubococcygeus muscle exercises and biofeedback. We heartily agree that some patients may be able to avoid surgical repair by diligently adhering to exercise program. Additionally, you correctly observed that ours was a study with a subjective endpoint, the patient's statement that she was continent or incontinent, which was not verified by urodynamic studies. I agree that we might have made important observations had we reported success rates after segregating patients with mixed-cause incontinence from those with pure anatomic incontinence.

Dr. Blanchette, I do not know whether we can anticipate a decline in the incidence of urinary stress incontinence because today's women have fewer pregnancies, receive better obstetric care, exercise regularly, and are generally more concerned with their health. However, because of increased life expectancy, we doctors will still have many patients with incontinence in our care.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

The physiologic mechanisms of variable decelerations

Robert H. Ball, MD, and Julian T. Parer, MD PhD
San Francisco, California

OBJECTIVES: The purpose of this study was to determine the cause and physiologic consequences of variable decelerations.
STUDY DESIGN: Previous studies of heart rate changes in human and experimental animals were critically reviewed with respect to the autonomic nervous system component, the cause of the increased vagal activity, and the role of cord compression or other stimuli in these heart rate changes.
RESULTS: There is abundant evidence from experimental and human studies that variable decelerations can be reproduced by either cord compression or head compression. The vagal reflex produced is probably caused by a combination of chemoreflex (earlier in the deceleration) and baroreflex (later). The variable deceleration is accompanied by an acidosis, primarily respiratory, and probably hypoxemia. Cord compression results in decreased umbilical blood flow.
CONCLUSIONS: Recent Doppler velocimetry studies suggest that even though the variable decelerations may be similar in duration and depth, the reduction of umbilical blood flow may be greater when the prime cause is cord compression than when the prime cause is vagal reflex from another source. (AM J OBSTET GYNECOL 1992;166:1683-9.)

Key words: Variable decelerations, cord occlusion, head compression, Doppler ultrasonography

Variable decelerations of the fetal heart rate (FHR) are characterized by their abrupt onset and recovery, variable shape, and variable relationship to contractions.[1] In contrast to late decelerations they are considered less ominous because their association with fetal acidosis appears to be weaker.[2] There is general agreement that variable decelerations are produced by a vagal response of the fetus. However, the stimulus for the vagal activity is less certain. In this report we will examine the evidence for the mechanisms of variable decelerations and discuss the potential importance of different mechanisms in the management of the fetus during labor.

Umbilical cord occlusion

Barcroft[3] in 1947 occluded the umbilical cord of the fetal goat, producing a deceleration of a type now considered as variable deceleration, which was abolished by vagotomy. Since then numerous investigators have performed studies involving occlusion of the umbilical cord or its component vessels in both experimental animals and humans. The studies have been carried out on either anesthetized or chronically prepared animals, the occlusion has been partial or complete, and the duration of occlusion has varied from several seconds up to 1 hour. In a number of the studies fetal blood pressures and arterial blood gases have also been measured. In addition, the involvement of the autonomic nervous system has been examined.

Heart rate changes during umbilical cord occlusion. As with the work of Barcroft, the majority of workers have reported an abrupt decrease in heart rate with cord occlusion. Studies have been carried out in fetal sheep,[4-9] goats,[10] baboons,[11] and humans.[12, 13] The duration of occlusion has ranged from 5 seconds to >60 minutes, and either umbilical arteries alone, umbilical veins alone, or the whole of the umbilical cord has been occluded. In some cases the occlusion is described as partial and in other cases as complete.

The responses to umbilical arterial occlusion are similar, when reported, to those of umbilical cord occlusion of all vessels. The initial response is a decrease in heart rate, although some workers under some conditions have reported a tendency for fetal heart rate to return toward normal values. Thus Towell and Salvador[10] noted that there was a bradycardia for the first 5 minutes of occlusion, but this reverted toward normal in the second 5 minutes of occlusion. Ball et al.[9] noted that the initial bradycardia returned toward a normal heart rate approximately 10 minutes after severe umbilical arterial occlusion producing an oxygen satura-

6/6/37491

tion below about 10% in the fetal arterial blood. Goodlin and Lowe[13] noted a deceleration with subsequent acceleration with 1 to 2 minutes of occlusion in the premature human fetus.

With respect to umbilical vein occlusion alone, most workers similarly report an abrupt drop in heart rate. However, there are some exceptions, and James et al.[11] in the anesthetized (fluothane) fetal baboon noted that with partial mild occlusion of the umbilical vein that there was a tachycardia, although with complete occlusion there was a bradycardia. Their occlusion was from 0.2 to 7.7 minutes and the time course of changes is not stated. Künzel et al.[5] noted that there was only a drop in heart rate with umbilical venous occlusion when the fetal arterial oxygen saturation was <40%. De Haan et al.[6] noted that there was a delayed drop in heart rate with umbilical venous occlusion.

Fetal arterial blood pressure changes during umbilical cord occlusion. With umbilical arterial or umbilical cord occlusion involving all vessels, there is an increase in arterial blood pressure.[4, 6, 7, 9, 10, 12] De Haan et al.[6] noted that bradycardia occurred within 1 to 2 beats of cord occlusion, in close association with the hypertensive response.

With umbilical venous occlusion, there tends to be a decrease in fetal arterial blood pressure.[4, 12] James et al.,[11] however, noted a decrease in arterial blood pressure only with partial, mild occlusion of the umbilical vein and an increase in arterial blood pressure with complete occlusion in anesthetized baboons.

A number of workers over the years have theorized that partial occlusion of the whole umbilical cord will initially compress the vein but not the artery, because of the lower blood pressure within the vein. Then more complete occlusion is presumed to effect the arterial flow as well. While this is a reasonable theory, it has not yet been demonstrated with differential flows in the artery and the vein during partial and complete compression maneuvers.

The majority of studies have involved cord occlusion for relatively brief periods. Few studies of cord occlusion have been carried out for prolonged periods of up to and more than 1 hour. At moderate degrees of occlusion (33% reduction of control umbilical arterial flow) Itskovitz et al.[7] demonstrated tachycardia. With increased occlusion (67% reduction of flow) hypertension with a decrease in FHR was noted; FHR recovered after 15 minutes. In contrast, Ball et al.[9] occluded the cord to produce severe fetal hypoxemia with arterial oxygen saturations <10% and with adjustment of the degree of occlusion to prevent catastrophic falls in arterial blood pressure. In these studies the aim was to reduce cerebral oxygen consumption to a point where fetal brain damage would occur. Preliminary studies suggest that fetal seizure activity, as an index of fetal brain damage, occurs when the initial hypertension produced by cord occlusion reverts to control values. This is in contrast to fetal hypoxemia produced by uterine arterial occlusion.[14] Under these conditions a fetal hypotension of approximately 10 mm Hg below control values always occurred when there was subsequent seizure activity.

Arterial blood gas changes during umbilical cord occlusion. Most workers report hypoxemia, hypercarbia and acidosis with either complete or partial umbilical cord occlusion,[5, 7, 11] when measurements were made. In some cases the degree of blood gas and acid-base abnormality has been used as an index of the degree of occlusion.[8, 10]

Itskovitz et al.[15] documented the influence of cord occlusion on umbilical arterial and venous oxygen contents; even with reductions of blood flow of 80% by cord occlusion there is no reduction in umbilical venous oxygen content, whereas umbilical arterial oxygen content is reduced by >60%. Similar observations can be made in human newborns after a series of severe variable decelerations or prolonged bradycardias. Presumably in these latter cases there is reduced umbilical blood flow, allowing time for the sluggishly moving blood to equilibrate with maternal blood in the placenta.

Although data on arterial blood gases during human cord occlusion are not available, there are some data on fetal scalp blood gases taken during variable deceleration complexes during labor.[16] There is a decrease in pH by the end of a variable deceleration, but this resolves over the next several minutes. The acidosis is primarily due to a concomitant elevation of carbon dioxide.[17]

The role of the autonomic nervous system in heart rate and blood pressure changes during umbilical cord occlusion. Since the initial work of Barcroft[3] showing that vagotomy altered the initial bradycardia produced by cord compression, thus demonstrating the role of the vagus in producing the bradycardia, a number of other workers have confirmed this either by surgical[4] or pharmacologic vagotomy.[6, 13] Investigators have also concerned themselves with whether the initial bradycardia is caused by chemoreceptor influence (because of the hypoxemia) or whether the baroreflex is responsible because of the rapid increase in arterial blood pressure. Itskovitz et al.[7] make a good case for the bradycardia during partial cord occlusion being initially due to the chemoreflex and later being due to the baroreflex, because there was a decrease in fetal oxygen content but no specific blood pressure elevation for about 30 seconds.

In considering the mechanical changes during cord occlusion, in compression of the umbilical artery there will be an increase in resistance, and this will manifest

as an increase in arterial blood pressure. Should there be only partial cord occlusion, with compression of the umbilical vein but not the artery, then there will be a decrease in venous return to the heart. This may result in a fetal hypoxemia that could then be responsible for a chemoreceptor-produced bradycardia. As noted above, however, it is impossible to know in any particular situation of partial cord occlusion what the differential arterial and venous umbilical blood flows are because this has not yet been measured.

There has been some work on the role of the sympathetic nervous system in the cardiovascular changes produced by umbilical cord occlusion. De Haan et al.[6] used α-adrenergic blockade during umbilical cord occlusion and found that there was still an initial increased blood pressure but that this decreased subsequently. In umbilical cord occlusion in anesthetized baboons, James et al.[11] noted that with partial mild occlusion there was an increase in FHR, which was prevented by sympathetic blockade with propranolol (a β-adrenergic blocker) or phentolamine (an α-adrenergic blocker). From the evidence presented one could conclude that during the vagally-produced bradycardia there is simultaneous sympathetic chronotropic activity that is less and that this is masked by the intensity of the vagal bradycardia.

Amnioinfusion and other clinical evidence of cord occlusion. There have been attempts to correlate umbilical cord position at delivery with the presence of variable decelerations in labor. In one study population,[18] 28% of fetuses were found at delivery to have a cord position that was felt to be susceptible to compression. However, there was no convincing evidence that the incidence of variable decelerations was greater in the group with "abnormal" cord position. The authors described a heart rate pattern consisting of accelerations and variable decelerations, and this finding was significantly associated with an abnormal cord position. They felt that these changes occurred with mild occlusion of the cord.

Gabbe et al.[19] documented the association of oligohydramnios and variable decelerations in a chronic rhesus monkey preparation and felt this was caused by cord compression. When amniotic fluid volume was replaced through an indwelling catheter, the variable decelerations were virtually abolished. The logical extension of this work was to investigate whether replenishing amniotic fluid in the uterine cavity in humans would reduce the incidence of variable decelerations. In 1985 Miyazaki and Nevarez[20] reported on the results of a randomized trial of amnioinfusion in patients with variable decelerations in labor. With an infusion of 800 ml of normal saline solution over 40 to 60 minutes, variables were abolished in 51% of patients compared with 4.2% that resolved spontaneously in the nontreatment group. Nageotte et al.[21] in the same year also found amnioinfusion in preterm fetuses to be successful. They randomized a group of patients with preterm premature rupture of membranes to treatment with amnioinfusion or control during labor. They documented a significantly lower incidence of variable decelerations in the treated group. The premise is that amnioinfusion provides renewed cushioning for the umbilical cord, protecting it from compression. Its apparent success provides indirect evidence for the role of cord compression in the origin of variable decelerations.

The influence of fetal head compression

It has been known for over 150 years that compression of the fetal vertex appears to be associated with decelerations in heart rate. It has been speculated that compression of the brain leads to "activation of vagal centers."[22] In 1933 Rech[23] elicited fetal bradycardia that mimicked variable decelerations of varying severity by adjusting the force of the squeeze with his hand on the fetal vertex. Chung and Hon[24] refined this by placing hard pessaries in the vagina of women in advanced labor. In between contractions pressure was exerted on these pessaries, compressing the fetal vertex. This led to variable-type decelerations in 18 of 19 attempts. They felt this was similar to the pressure exerted by the dilating cervix. Further evidence in their minds for vagal stimulation by head compression was the consistent decelerations noted with the locking of forceps and initiation of traction.

Paul et al.[25] studied this phenomenon in anesthetized fetal sheep. Manual compression of the fetal vertex was performed for 20 to 50 seconds. Carotid blood flow decreased markedly with the compression, and blood pressure increased as profound bradycardia ensued. The investigators believed that this apparent vagal response could be either baroreceptor or chemoreceptor mediated. Mann et al.[26] used a metal clamp to apply pressure to fetal sheep heads. They found no consistent changes in heart rate, but cerebral blood flow and metabolism decreased as did cerebral oxygen consumption.

The fact that variable decelerations cannot be effectively abolished by amnioinfusion in the second stage of labor supports the view that head compression is a mechanism for variable decelerations.[21] Kelly[22] speculated that bradycardia with head compression was an appropriate physiologic response. With increased diastole, according to him, blood flow through the foramen ovale and the ductus arteriosus changes so as to shunt more oxygenated umbilical venous blood to the brain. In contrast, Goodlin and Haesslein[27] suggested several additional mechanisms for variable decelerations, including fetal Valsalva maneuver and maternal activities

such as voiding and seizures. They felt that some of the bradycardias may be "adult" reflexes that are inappropriate for the fetus and may result in reduced fetal blood flow and oxygenation.

Cardiac output regulation

It has commonly been stated that in the fetus the cardiac output is closely related to heart rate. In adults the beat-to-beat amount of blood pumped by the heart is determined by the amount of blood returning to the heart. In accordance with the Frank-Starling mechanism, when the cardiac muscle is stretched before contraction by an increased inflow of blood, it contracts with a greater force than before and is able to pump out more blood. In other words, the heart pumps all the blood that flows into it without excessive damming of blood in the veins. This mechanism has been studied in unanesthetized fetal lambs and has been shown to be less developed than in adult sheep. The imperfect mechanism in the fetal lamb is probably due to the fact that the heart muscle is not as well developed as in the adult sheep. It is likely that the same is true of a human fetus, as it is generally more immature than a fetal lamb when born. As a consequence, increases in the filling pressure or preload produce minor, if any, changes in combined ventricular output, suggesting that the fetal heart normally operates near the top of its function curve.

The relationship between FHR and cardiac output has not been confirmed in human fetuses under physiologic conditions, because the spontaneous increase in heart rate has been found to be associated with a decrease in stroke volume, maintaining the cardiac output unchanged.[28]

In addition to heart rate and preload, cardiac output depends on afterload and intrinsic contractility. The fetal heart appears to be very sensitive to changes in the afterload, represented by the fetal blood pressure. In this way, increases in afterload dramatically reduce the stroke volume or cardiac output. As has already been stated, the fetal heart is incompletely developed compared with that of adults. Many ultrastructural differences between the fetal and adult heart account for a lower intrinsic capacity of the fetal heart to contract. Each of these four determinants of cardiac output do not work separately, but rather they interact dynamically to modulate the fetal cardiac output during physiologic conditions.[29]

On the basis of clinical observations, it appears that the fetus can generally tolerate decelerations or bradycardias that are not <80 beats/min presumably because of the above compensatory interactions. However, at severely reduced heart rates, particularly <60 beats/min, it is likely that fetal cardiac output, and hence umbilical blood flow, cannot be maintained. Thus a deceleration of heart rate <60 beats/min either due to cord occlusion or reduced fetal cardiac output, will signify insufficiency of umbilical blood flow.

Evidence from Doppler velocimetry studies

In recent years, the ratio of systolic-to-diastolic velocity profiles in various fetal and maternal vessels has been used as an index of vascular resistance. That is, when the systolic/diastolic ratio increases, increased vascular resistance is one of the causes, and this has been used to indicate fetal hemodynamic compensations. It is now quite clear that a change in vascular resistance is only one of the components giving rise to changes in systolic/diastolic ratios, other features being a prolonged cardiac cycle, compliance of the vascular system, kinetic reflection of the velocity wave, and possibly other factors.[30]

In fetal sheep the systolic/diastolic ratio has been studied during short-term occlusion of both the umbilical vessels and the uterine artery.[8] During total umbilical vessel occlusion for 60 seconds there was a bradycardia and an increase in the systolic/diastolic ratio. The heart rate changes mimicked variable decelerations. The systolic and diastolic velocities both fell, but the diastolic velocity fell more than the systolic, leading to an increase in the systolic/diastolic ratio. The authors speculated that the fall in diastolic velocity was an indication of increased downstream resistance occasioned by the umbilical arterial compression and that the fall in systolic velocity was evidence of pump compromise. In contrast to this, uterine artery occlusion produced fetal hypoxemia, with a decrease in both systolic and diastolic velocities giving little change in the systolic/diastolic ratio. The FHR change mimicked late decelerations. The authors speculated that this change was produced not by an increase in resistance to perfusion on the fetal side of the placenta but was consistent with a decrease in fetal cardiac output and umbilical blood flow.

Weiss et al.[31] studied eight women in labor all of whose fetuses were demonstrating variable decelerations. They were in the active phase of labor with cervical dilatation between 2 and 7 cm. The authors describe a number of technical difficulties in measuring the velocity profiles in these fetuses and freely discarded invalid data. In six of the eight women there was an increase in the systolic/diastolic ratio with reversed diastolic flow, indicating that there was no net forward flow. The increase in the systolic/diastolic ratio began before the decrease in FHR. The authors concluded that this was consistent with the general theory of mechanical obstruction of the umbilical cord producing an increase in afterload and resistance, resulting in the bradycardia. In the other two of the eight women studied there was an increase in the systolic/diastolic

ratio, but this could be explained on the basis of a heart rate effect. If the systolic/diastolic ratio was corrected for that prolonged cardiac interval due to the bradycardia, there was no change in the systolic/diastolic ratio. The authors felt that this latter pair of fetuses had a moderate decrease in flow due to local or systemic hypoxemia of the fetus. The implication is therefore that these fetuses did not have variable decelerations due to cord compression but rather some other vagal activity, possibly due to hypoxemia.

Comment

Variable decelerations are vagally mediated. The vagal response may be due to either chemoreceptor or baroreceptor input. Possibly the initial deceleration (that is, the first seconds) may be due to chemoreceptor activity and the persistence of the deceleration due to baroreceptor activity.

Cord occlusion is a likely cause of many variable decelerations. We theorize, however, that this is particularly true of the first stage active phase of labor. Cord occlusion, either partial or complete, can cause both increases in afterload and decreases in fetal arterial oxygen content, both of which will result in the vagal activity causing the bradycardia. There may also be a sympathetic discharge, both α- and β-adrenergic, responsible for the hypertension in the case of the former and tendency toward increased heart rate in the case of the latter. However, the vagal influence is greater and, therefore, the net result of this is a deceleration.

Head compression is a likely cause of many variable decelerations. We theorize that this is particularly true in the second stage of labor, when cord compression is unlikely in many cases. Head compression causes a vagal discharge due to dural stimulation. This vagal discharge causes a bradycardia. If this is sufficiently severe the bradycardia may result in decreased fetal cardiac output and umbilical blood flow due to the relatively poorly developed Frank-Starling mechanism at low heart rates in the fetus.

In the case of mild to moderate variables (that is, with the FHR not <60 beats/min), the significance of these purely vagal decelerations may well be less than that of the cord occlusion variable decelerations. As yet there is no information regarding fetal acid-base changes with the two types of variable decelerations. Such data could be gained by fetal blood sampling during two types of variable decelerations as distinguished by Doppler velocimetry.

Distinguishing the types of variable decelerations may have important practical significance, because if it can be shown that the head compression decelerations are more benign, this would allow more conservative management of the second stage of labor, where they probably most frequently occur.

Discussion

DR. E. PAUL KIRK, Portland, Oregon. This is an elegant review of the current understanding of the physiologic mechanisms of variable decelerations. Continuous electronic FHR monitoring has been with us now for more than two decades, and the fact that it has become a standard part of obstetric practice has in no way lessened our need to understand the physiologic basis for the patterns that we see and react to on a daily basis. Our ambivalence toward the use of continuous monitoring is characterized by the observation that its widespread use has been accompanied on the one hand by a rise in cesarean section rates with little apparent impact on long-term sequelae and on the other hand by the virtual elimination of intrapartum death and a vast personal and anecdotal experience where fetal monitoring appears to have been invaluable in individual cases.

Continuous electronic FHR monitoring is part of our lives on the labor and delivery floor. Fifty percent of tracings show some abnormality, and the challenge has to be not only to accurately report what we see but also to strive to understand what we are seeing and to understand the etiology of abnormalities and their physiologic basis so that the tracing can be intelligently interpreted in the context of the individual circumstance and within the perspective of the particular stage of labor. Dr. Parer has been in the vanguard of the movement, demanding intelligent interpretation of, rather than blinkered reaction to, abnormal tracings, and this paper represents another excellent contribution in that genre.

The authors describe the observed effects of partial and complete occlusion of the arterial and venous umbilical vessels, namely, an abrupt bradycardia of variable duration. They describe the consequences in terms of the blood pressure responses and the production of hypoxemia, hypercarbia, and acidosis. They recall the early work that demonstrated the effect of medical and surgical vagotomy and the suggestions of an early baroreceptor and later chemoreceptor effect. They draw some analogies from clinical observations in the second stage of labor and the effects of amnioinfusion. They emphasize the relatively incomplete development of the fetal heart and its sensitivity to afterload changes, but they seem unable to draw any convincing conclusions from Doppler velocimetry studies. Finally, they reconcile the data by reaffirming two separate etiologies for variable deceleration, making a likely association of first-stage events with cord occlusion and second stage events with head compression, and suggesting a practical importance in attempting a distinction between the two types of variable decelerations.

The obvious response is to ask how those distinctions might be made. I believe that the practice obstetrician is often frustrated by the apparent difficulty in bridging the gap between the evidence provided by animal laboratory experimentation and the realities of the labor and delivery suite. Could Dr. Parer suggest some further area of investigation so that the distinctions might be more easily made? Might we expect more helpful information as Doppler velocimetry techniques become better refined and might we learn something from observing intrapartum breathing patterns, given that the midbrain is the site of reception and integration of chemoreceptor and baroreceptor inputs and that the cardiovascular centers in the pons and medulla are heavily influenced by activity in the respiratory centers. The authors appear to place some weight on the observation that the fetal stroke volume lies at the breakpoint of the function curve and implies that this is a unique circumstance, although it is my understanding that the supine adult as opposed to the upright adult shows the same curve as the fetus. Finally, is it fair to describe the sensitivity of the fetal heart to afterload charges as applying to both ventricles? Work by Thornburg at our institution showed this sensitivity to apply to the right ventricle, whereas the left ventricle which supplies most of the blood flow to the brain maintained its stroke volume in the face of elevated aortic pressures.[1, 2]

Those of you who appreciate my inadequacies as a physiologist will be suspicious of the detail of some of these questions and will recognize the hand of my colleague, Dr. John Bissonnette, in their inquiry. Perhaps that is an appropriate reminder as to how dependent we journeymen clinicians are on the insights provided by fetal physiologists such as Dr. Parer. I look forward to the next article in the hope that the author will make the ultimate distinction between significant and insignificant variable decelerations.

Dr. Robert Goodlin, Placerville, California. The fetal baroreflex has been studied and reviewed for more than 100 years, but little new information has been added in the past 25 years.[1] Besides producing acute fetal bradycardia, vagal stimulation also increases fetal beat-to-beat variability. I have wondered why during severe acute fetal bradycardia, fetal beat-to-beat variability is often not increased, but sometimes is even decreased. Does this have any prognostic significance as to fetal health? Because Dr. Parer mentioned my article on inappropriate fetal bradycardia, I wonder if he too is now willing to inhibit apparently detrimental fetal vagal bradycardia with atropine?[2] Because amnioinfusion is much less efficient than atropine in inhibiting severe fetal bradycardia, I also wonder if amnioinfusion really inhibits vagal fetal stimulation.

Dr. Parer (Closing). I would first like to make a semantic comment about abnormal FHR patterns. We don't really know what an abnormal pattern is. Mild variable decelerations do not cause acidosis and also can hardly be called abnormal. Vagal reflex late decelerations that do not cause acidosis should not be termed abnormal. A better term might be "variant" heart rate patterns.

Regarding the cardiac output of the fetus during bradycardia, it is possible that the right and left ventricles may have different responses, as Dr. Kirk has pointed out. He notes that maintenance of left ventricular output under these conditions would be valuable for maintaining blood flow to the brain and heart. Although such data are not yet available for the human under such specific conditions as second stage variable decelerations, this could be an explanation why they may be a more benign process for the fetus than cord compression variable decelerations.

Dr. Kirk asks how we may clinically distinguish between variable decelerations produced by cord compression and the purely vagal type. I would like to think that Doppler velocimetry holds the key. However, when I look at the work of Weiss et al. and what they had to go through to get data on eight patients and the amount of information they had to discard to get clean studies, I would think that the journeyman obstetrician would be unable to get clinically useful observations in the second stage of labor. The technical difficulties are too great. Maybe it is sufficient to maintain that second stage patterns are these that are purely produced by the vagus nerve and that we should be more conservative in our approach to the second stage variable deceleration. That is, we should not cry fetal distress and put the forceps on after a brief period of such variable decelerations. It is a clinical observation that the well-grown fetus at term can tolerate, in the vast majority of cases, at least 30 minutes of severe variable decelerations. If purely of the vagal type, they may be tolerated for a lot longer. Additionally, in a clinical setting you would be able to rescue the decompensating fetus in a reasonably quick period of time, either by an operative vaginal delivery, by discouraging pushing with every contraction, or by short-term tocolysis. I hope that further work will strengthen the concept of the two causes of variable decelerations and that some technique for clinically distinguishing them will emerge.

Dr. Goodlin wonders that if there is an increase in vagal activity during these variable decelerations in the second stage, can we detect an increase in FHR variability compared with first-stage variable decelerations? To my knowledge that has not been shown. In any case, I am not sure that an increase in vagal activity will cause an increase in variability. Rather, the vagus is transmitting increased activity from another source. However, differences in variability in the two types would be worth looking at.

I am not yet ready to give these patients atropine in the second stage. The data are not yet available to show that such treatment is beneficial. Another problem is that once you have given the atropine, the effect remains for a long time, and you lose the heart rate tracing that you are using to follow the condition of the fetus. You can get into multipharmacology obstetrics and give drugs to subsequently counteract the atropine, but I think that is going too far.

As I noted earlier, amnioinfusion was not as effective in the second stage as it was in the first stage.

Elective induction versus spontaneous labor: A retrospective study of complications and outcome

James A. Macer, MD, Cynthia L. Macer, MD, and Linda S. Chan, PhD
Pasadena, California

OBJECTIVE: This retrospective study was undertaken to identify whether electively induced labor places the mother or her fetus at increased risk as compared with her spontaneous labor cohort.
STUDY DESIGN: This study compares the labor, delivery, and fetal outcome of 253 parturients in which labor was electively induced with 253 matched controls who began labor spontaneously. All patients were delivered at Huntington Memorial Hospital in Pasadena, California, during the calendar year 1990. The patients were between 37 and 41 weeks' gestation and had no medical or obstetric conditions necessitating induction. The cases and controls were matched for age group, parity, gestational age, and delivering obstetrician.
RESULTS: Epidural anesthesia was used in 83.8% of patients in the induction group versus 55.7% in the spontaneous group. Patients with labor induced had a shorter first stage of labor. Meconium staining was found significantly more often in the spontaneous group than in the induced group (16.2% vs 6.7%). This contributed to a greater rate of neonatal consultations in the spontaneous labor group. Although cesarean section rates between the two groups were similar, nulliparous patients in the induction group with an estimated Bishop score of ≤5 had a 50% cesarean section rate. Iatrogenic prematurity was not encountered. No differences existed between the two groups with respect to intrapartum maternal complications, fetal complications, or postpartum complications.
CONCLUSIONS: When compared with spontaneous labor, elective induction of labor at term does not appear to pose an increased risk to the mother or her fetus in a carefully selected patient population. However, elective induction of labor in a nulliparous patient with an unfavorable cervix should be discouraged. (AM J OBSTET GYNECOL 1992;166:1690-7.)

Key words: Elective induction, induction, oxytocin, meconium staining, epidural anesthesia

Induction of labor is a valuable and important clinical tool in obstetrics. It is a well-accepted therapy when initiated for a medical or obstetric indication. When induction of labor is done for convenience or psychosocial reasons, it is elective and is controversial.

The rate of induction is on the rise,[1, 2] with an increasing number of obstetricians and their patients choosing to electively induce labor. At Huntington Memorial Hospital, a tertiary care center, 30% of the inductions done in 1990 were done electively without obvious medical or obstetric indications.

Although the literature on elective induction is limited, advantages and disadvantages have been described.[3-5] Opinions differ regarding the risk to mother and fetus during elective induction of labor.[1, 4-7] This retrospective study was undertaken not to validate or promote elective induction but rather to identify whether electively induced labor places the mother and her fetus at increased risk as compared with her spontaneous labor cohort.

Patients and methods

The patients in this study were delivered at Huntington Memorial Hospital in Pasadena, California, during the calendar year 1990. Huntington Memorial Hospital is a private tertiary care facility with 5561 deliveries during the year 1990.

The patients in the study group were identified by examining hospital lists of patients undergoing elective induction of labor. The charts were then individually reviewed to determine eligibility. Patients selected were required to have a singleton, cephalic presentation with a gestional age between 37 and 41 weeks without any medical or obstetric conditions necessitating induction. The exclusion criteria are listed in Table I. This resulted in an elective induction group of 266 patients.

Each patient in the induction group was then individually matched with a patient with the same eligibility criteria and whose labor had begun spontaneously. They were matched for age (±4 years), parity, gestational age (±1 week), and delivering obstetrician. The

Table I. Exclusion criteria for study and control groups

Obstetric
Previous cesarean section or uterine scar
Multiple gestation
Noncephalic presentation
Fetal growth retardation
Spontaneous rupture of membranes, not in labor
Postdates
Oligohydramnios
Polyhydramnios
Abnormal antepartum testing
Use of tocolytic therapy within 4 wk before labor
Medical problems
Pregnancy-induced hypertension and preeclampsia
Gestational and type I diabetes
Chronic hypertension
Hemoglobin <10 gm/dl
Any serious illness or medical problem (e.g., epilepsy, cardiac diseases)

spontaneous labor control group was chosen from hospital lists of patients with spontaneous labor. The first suitable match was taken in each case by a person independent of this study. No match could be found for 13 of the patients undergoing labor induction; they were therefore excluded. This left 253 patients in each group.

For the purpose of this study, induction was defined as the initiation of labor in a woman with intact membranes and no regular uterine contractions. A Bishop score[8] of ≤5 or >5 was estimated on each patient in the induction group. This was based on the patient's initial recorded cervical examination before the induction was started. The methods of induction could include artificial rupture of the membranes, oxytocin infusion, prostaglandin E_2 gel or suppositories, or any combination thereof. Spontaneous labor in the control group was defined as the onset of regular uterine contractions 5 minutes apart with or without rupture of membranes. The number of patients in the control group requiring oxytocin augmentation was also recorded.

The data gathered on all 506 patients were obtained through extensive review of patient records. This included the labor, delivery, and postpartum records and nursing notes and parturition summaries dictated by the obstetrician. Labor abnormalities were defined by Friedman's criteria.[9] Fetal distress was defined as an abnormality of fetal heart rate necessitating that the obstetrician terminate labor by assisted vaginal delivery or cesarean section.

The data were entered into a computer and the BMDP and EPI-INFO softwares were used for statistical analysis. The paired t test was used to compare groups for continuous variables. The odds ratio analysis for case control study was used to compare groups for discrete variables.

Table II. Comparison of matching criteria between groups

	Induction group (N = 253)	*Spontaneous group (N = 253)*
Maternal age (yr)		
Average	29.90	29.85
SD	4.92	4.67
Parity (%)		
Nulliparous	30.4	30.4
Multiparous	69.6	69.6
Gestational age (wk)		
Average	39.43	39.32
SD	1.02	0.90

Table III. Method of induction

Type	*No.*	*%*

Oxytocin plus artificial rupture of membranes	21	8.3
Artificial rupture of membranes	6	2.4
Prostaglandin	4	1.6
Prostaglandin plus oxytocin	9	3.6
TOTAL	253	100.0

Results

Study group profile. The patient profiles of both groups were comparable for age, parity, and gestational age, as shown in Table II. A total of 26 obstetricians was represented. The number of pairs per physician varied from one (0.4%) to 28 (11.1%). Twelve of the 26 physicians contributed 82.2% of the patients.

Induction profile. Oxytocin alone or in combination with artificial rupture of membranes was the method of induction used in 234 of the 253 patients (92.5%) (Table III). Within the induction group, 24.1% (61/253) of the patients had an estimated Bishop score of ≤5, and 75.9% (192/253) had a score of >5.

Labor. The length of the first stage of labor was shorter in the induction group than in the spontaneous labor group, 6.0 versus 7.2 hours ($p = 0.008$). No differences in duration of the second stage of labor were found between the groups. The duration of ruptured membranes was also similar between the two groups, 5.6 hours for the induction group and 5.0 hours for the spontaneous labor group (Table IV). In addition the numbers of reported vaginal examinations during labor were similar, 5.2 (±2.1) for the induced and 5.0 (±2.1) for the spontaneous labor patients. In the spontaneous labor group 40% of the patients received oxytocin augmentation.

The use of epidural anesthesia was statistically different between the two groups. In the induction group, 83.8% (212/253) used epidural anesthesia, whereas 55.7% (141/253) used epidural anesthesia in the spontaneous labor group ($p < 0.001$) (Table V).

Table IV. Duration of first and second stages of labor and ruptured membranes

	*No. of pairs**	*Induction group (mean ± SD)*	*Spontaneous labor group (mean ± SD)*	*Significance*
First-stage labor (hr)

*Percent of total patients receiving epidural anesthetic.

Table VI. Percentage distribution by mode of delivery for subgroups defined by parity

	Induction group	*Spontaneous group*	*Significance*
Nulliparous			
No. of cases	77	77	
Primary cesarean section (%)	33.8	22.1	NS ($p = 0.15$)
Forceps-assisted plus vacuum-assisted vaginal delivery (%)	36.4	31.2	NS
Multiparous			
No. of cases	176	176	
Primary cesarean section (%)	6.2	6.2	NS
Forceps-assisted plus vacuum-assisted vaginal delivery (%)	23.9	16.5	NS

NS, Not significant.

Delivery. The primary cesarean section rate was 14.6% for the induction group and 11.1% for the spontaneous group (Table V). The assisted vaginal delivery (vaginal forceps or vacuum) rate for the induction group was 27.7% and 20.9% for the spontaneous labor group. There was a significant difference in spontaneous vaginal delivery rates between the two groups, 57.7% for the induction and 68% for the spontaneous labor group ($p = 0.02$). This translates to a significantly higher combined assisted vaginal delivery and cesarean section rate for the induction group than for the spontaneous labor group (42.3% vs 32.0%, $p = 0.02$). However, when only patients receiving epidural anesthesia in both groups were considered, the rate of combined cesarean section and assisted vaginal deliveries was nearly identical, 47.6% (101/212) in the induction group and 48.2% (68/141) in the spontaneous labor group (Table V).

When the role of parity and the mode of delivery were analyzed, the nulliparous patient in the induction group had an indication toward a higher cesarean section rate than the nulliparous patient in the spontaneous group, 33.8% compared with 22.1% ($p = 0.15$). The multiparous cesarean section rates were the same, 6.2% (Table VI). No statistically significant differences were found in the rate of assisted vaginal delivery with respect to parity (Table VI).

The nulliparous patient with a Bishop score of ≤5

Table VII. Cesarean section deliveries by parity and Bishop score

Parity	*Induction group (Bishop score ≤5)*	*Induction group (Bishop score >5)*	*Spontaneous group*
Nulliparous	50.0% (12/24)	26.4% (14/53)	22.1% (17/77)
Multiparous	5.4% (2/37)	6.5% (9/139)	6.2% (11/176)

Numbers in parentheses indicate numerator and denominator of percent.

had an indication toward a higher cesarean section rate than those with a Bishop score >5, 50% compared with 26.4% ($p = 0.12\%$). The cesarean section rate for the nulliparous patient in the spontaneous labor group was 22.1%. The Bishop score did not appear to affect the cesarean section rate for the multiparous patient (Table VII).

The indications for a cesarean section were similar for both groups with the exception of the indication "primary arrest of dilatation." The induction group had five cesarean sections done for this indication, whereas the spontaneous group had none ($p < 0.01$ on the basis of the Poisson probability) (Table VIII). All five of the induction patients with primary arrest of dilatation were nulliparous with a Bishop score of ≤5.

The time of day that the deliveries occurred in the spontaneous labor group was evenly distributed over the 24-hour period. The induction group, however, had only 11% of its deliveries between midnight and eight AM (Fig. 1).

Conditions of fetus and newborn. All babies were born alive, and there were no neonatal deaths. There was no iatrogenic prematurity in the induction group. Fetal outcome is shown in Table IX. The mean birth weight of infants in the induction group was 3553 gm compared with 3434 gm in the spontaneous group ($p = 0.0007$). There were 33 babies whose birth weight was >4000 gm in the induction group and 21 in the spontaneous group.

There was no significant difference between the two groups in the number of cases with Apgar scores <7 at 1 or 5 minutes. Additionally, there was no difference in fetal heart rate abnormalities or other fetal complications. Meconium was found in 17 patients (6.7%) in the induction group but occurred significantly more often in the spontaneous labor group, 41 patients (16.2%) ($p = 0.0013$). In addition, a neonatal consultation was obtained in 17.4% of the cases in the spontaneous labor group, as opposed to 9.1% in the induction group ($p = 0.009$). The reasons for neonatal consultations are shown in Table X. Meconium was the reason for consultation in 15 (5.9%) of the induced patients and 34 (13.4%) of the spontaneous labor patients ($p = 0.007$). There were six neonatal intensive care unit admissions in the spontaneous labor group and two in the induction group. One baby in the induction group was admitted after shoulder dystocia, severe variable decelerations, and birth asphyxia (weight 3700 gm, Apgar scores 1 and 6). The other admission was for transient tachypnea and to rule out pneumonia. The infant did not have respiratory distress syndrome. In the spontaneous labor group three admissions were for amnionitis, one for meconium aspiration, one for birth asphyxia (Apgar scores 2 and 6), and one for respiratory difficulty. All infants were discharged home from the neonatal intensive care unit in good condition.

Table VIII. Indications for cesarean section

Indications	*Induction group*		*Spontaneous group*		*Significance*
	No.	*%*	*No.*	*%*	
Primary arrest of dilatation	5	2.0	0	0.0	$p < 0.01$
Secondary arrest of dilatation	12	4.7	10	4.0	NS
Arrest of descent	11	4.3	12	4.7	NS
Fetal distress	11	4.3	8	3.2	NS
Cord prolapse	2	0.8	1	0.4	NS
Malposition	0	0.0	1	0.4	NS
Other	0	0.0	1	0.4	NS

NS, Not significant.

Note: Some physicians reported more than one indication per case.

No significant differences between the two groups were observed for lacerations, intrapartum maternal complications, or postpartum complications (Table XI).

Comment

According to the American College of Obstetricians and Gynecologists, "Induction of labor is undertaken when, in the opinion of the physician, the risks of delivery to the mother or the fetus or both are less than the risk of continuing the pregnancy."[10] Elective induction of labor is performed before there exists a known risk to the mother or fetus of continuing the pregnancy. This procedure should be considered justifiable only after it is shown that there is no increased risk to the mother or fetus and that the benefits of success outweigh the disadvantages of failure.

Opinions differ regarding the risk to mother and fetus during elective induction of labor.[1, 3-7, 11, 12] Proponents of elective induction argue that they are avoiding potential adverse outcomes associated with postdates, preeclampsia, and term intrauterine fetal death of unknown causes.[6, 12, 13] Others advocate elec-

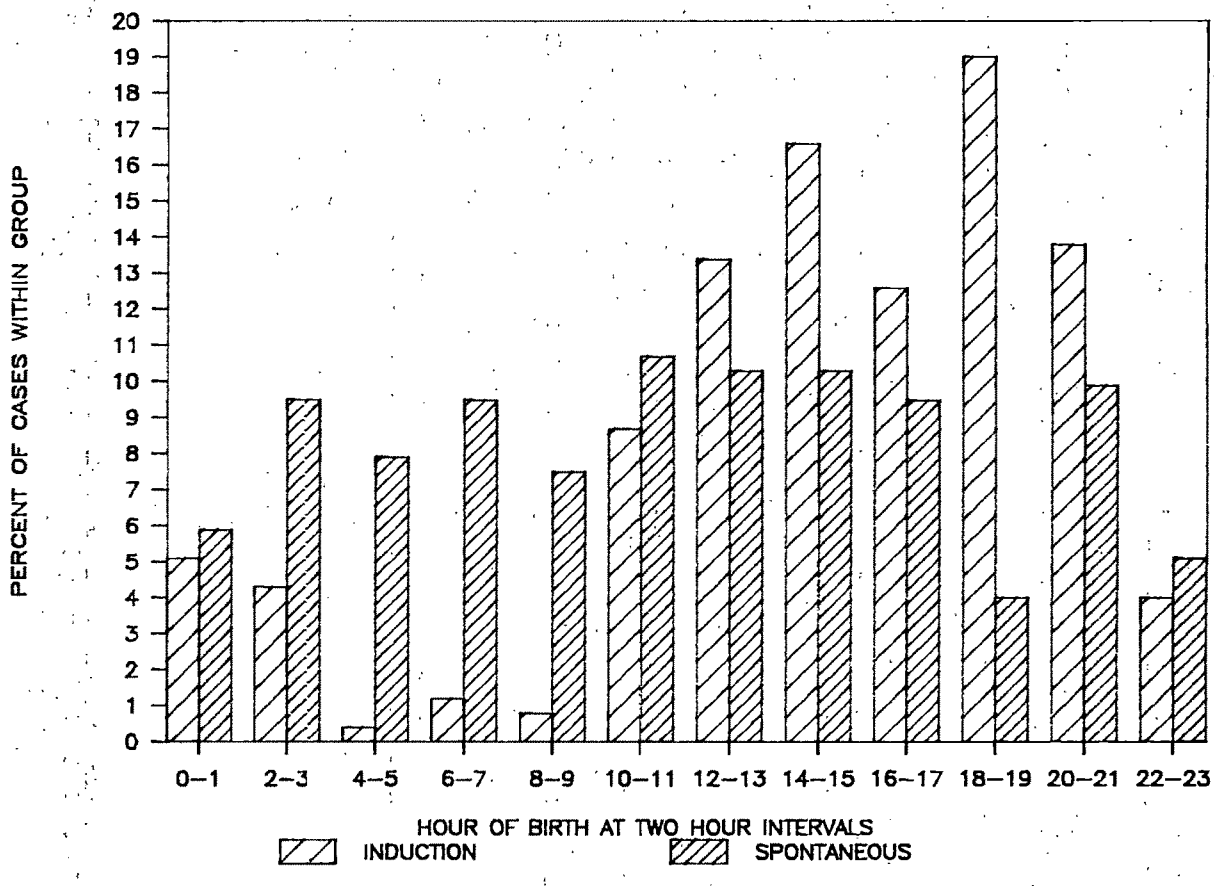

Fig. 1. Percentage distribution by hour of birth.

tive induction to allow for daytime deliveries with a rested patient and better perinatal medical care personnel.[3, 6, 14] It allows for better planning by the physician, patients, and their families. Patient anxiety may be reduced, resulting in a more pleasant birth experience by having her own physician present and planning for pain control with epidural anesthesia.

Those opposing elective induction would argue that not only is it generally not recommended by the American College of Obstetricians and Gynecologists or the Food and Drug Administration but also it is an unnecessary and unnatural process.[13, 15] There is concern over inducing labor before the fetus is mature or "ready." Smith et al.[3] expressed concern that once a physician has initiated one form of active intervention (the decision to electively induce labor) there may be a tendency to more readily accept further intervention in the form of operative or assisted deliveries.

Previous studies have cited difficulties in obtaining control groups comparable to the induction groups and controlling for differences in practice styles of individual physicians.[7, 12] In this study we felt confident that we attained a control group very similar to the induction group. All patients were considered low risk, with no medical or obstetric complications. They were matched closely for age, parity, gestational age, and physician, the latter in an attempt to minimize the physician style differences or tendencies of one physician to affect outcome of either group.

In this study the majority of the induced labor patients were delivered in the afternoon and early evening. The spontaneous labor patients were delivered evenly over the 24-hour period. Similar findings were also reported by other studies.[3, 5, 14]

One trend that appears fairly consistent throughout the literature is the increased use of epidural anesthesia in the induction group.[1, 3-5, 11] This study is consistent with previous findings, because 83.8% of induced labor patients received epidural anesthetic whereas only 55.7% of the spontaneous labor patients did so. A possible explanation may be that when patients agreed to planned or scheduled delivery many of them also planned for pain control.

The induced labor group of patients had a shorter first stage. This occurred more often in nulliparous patients.

We did not find a significant increase in the number of cesarean sections or assisted vaginal deliveries in the

Table IX. Fetal outcome

Outcome	*Induction group (N = 253)*	*Spontaneous group (N = 253)*	*Significance*
Birth weight (gm)

induction group. This is in contrast to results of Yudkin et al.[4] and Vierhout et al.[5] but similar to the findings of Sande et al.[1] and Martin et al.[6]

Patients in the spontaneous labor group had a greater chance of having a spontaneous vaginal delivery as opposed to an assisted vaginal delivery or cesarean section ($p = 0.02$). However, this appears to be related to the use of epidural anesthesia rather than the induction process itself. As described earlier, when only patients receiving epidural anesthetic in both groups were considered, the spontaneous vaginal delivery rates were nearly identical, 51.8% in the spontaneous group and 52.4% in the induction group.

Our results identified a group of patients undergoing induction who are at risk of having a cesarean section. Twenty-four nulliparous patients with a Bishop score of ≤5 underwent induction. Twelve of these patients (50.0%) required a cesarean section. If the nulliparous patients' Bishop scores were >5, the cesarean section rate was similar to that of nulliparous patients in the spontaneous labor group (26.4% vs 22.1%). Although the nulliparous patient with a Bishop score of ≤5 is at an increased risk of cesarean section, the multiparous patients' cesarean section rate did not differ with Bishop scores. Smith et al.[2] also found an increased cesarean incidence in the nulliparous patient.

Five patients in the induction group underwent a cesarean section for primary arrest of dilatation. No patients in the spontaneous labor group required a cesarean section for this diagnosis. All five of these patients were nulliparous with a Bishop score of ≤5.

Meconium staining was found more often in the spontaneous labor group. This accounted for an increase in delivery room consultations by a neonatolo-

gist. However, the presence of meconium did not appear to have an adverse effect on ultimate fetal outcome. This finding of increased meconium staining is fairly consistent throughout the literature.[3, 5-6, 11-15] One might hypothesize that a fetus under stress will initiate labor and thus explain the higher incidence of meconium staining in patients in spontaneous labor. With the induced labor patient labor may have been initiated before the fetus was stressed.

Although the average birth weight in the induced group was higher, this did not appear to affect delivery outcome. Fetal size may have contributed to the physician's decision to encourage induction before 41 weeks.

The two groups did not differ in fetal outcome as reflected by similar Apgar scores and complications. However, although the difference is not statistically significant, there were more neonatal intensive care admissions in the spontaneous labor group. Similar to findings in previous studies, there was no prematurity in the induction group.[3, 5] The maternal outcome was not adversely affected by induction, as indicated by the absence of increased intrapartum or postpartum complications.

In summary, when compared with spontaneous labor, elective induction of labor at term does not appear to pose an increased risk to the mother or her fetus in a carefully selected patient population. However, elective induction of labor in a nulliparous patient with an unfavorable cervix, should be discouraged.

We thank Henry Chiu, MS, for his efforts in acquiring case lists and data entry and Terry LeMoncheck for preparation of the manuscript.

Discussion

DR. JAMES D. FEARL, Portland, Oregon. What is an elective induction of labor? In this article the authors have defined it as being done for convenience or psychosocial reasons after medical or obstetric inductions are eliminated. He has retrospectively evaluated electively induced labor in the year 1990 at Huntington Memorial Hospital, where 5561 deliveries took place during the year and 30% of the inductions were elective. A list of medical problems and obstetric conditions stated in their Table I seems to include most or all the diagnoses representing the 70% of induced labors that would be considered nonelective. It was noted that macrosomia was not included in these exclusion criteria. These exclusion critera were also used to allow selection of a comparable control group of patients and to attempt to eliminate additional factors in the conduct of labor that might influence operative delivery.

The resulting 266 patients were reduced to 253 patients when no match could be found for 13 of the induction patients. One of the more common criticisms of elective induction studies in the literature is lack of a proper control group of patients. Each patient was matched with a control patient of comparable age (±4 years), parity (nulliparous or parous), gestational age (±1 week), and the same delivering obstetrician. Although possibly not important, frequency of smoking and drug use was not determined.

The differing opinions as to the acceptability of elective induction of labor on the basis of risk to mother and fetus have been debated for decades. This group of 253 patients and their well-matched controls were studied to determine whether a mother and fetus with elective induction are placed at increased risk in 1990.

Many aspects of labor and delivery were comparable in the two groups. Frequency of neonatal consultations, incidence of meconium staining, and admissions to the neonatal intensive care unit were favorable toward the induced patients.

To examine Dr. Macer's conclusion that elective induction of labor does not pose an increased risk to mother or fetus, the parameters of fetal distress and frequency of cesarean section must be looked at. The categories of fetal outcome listed as fetal complications or fetal indications for delivery by cesarean section include fetal heart rate abnormalities, fetal distress,

abruptio placentae, and cord prolapse. Although there was no statistical significance when any individual complication is compared with the controls, all categories except heart rate abnormalities were present more commonly in the induced group of patients.

Because there were 33 newborns weighing >4000 gm compared with 21 newborns in the spontaneous labor group, I would question Dr. Macer's conclusion that this did not affect the delivery outcome. If estimated fetal size contributed to the decision to induce the labor, I would not consider this an elective induction. Can you tell us how many of the ≥4000 gm infants were delivered by cesarean section? As he pointed out, the 24 nulliparous patients with an unfavorable Bishop score had a cesarean section rate twice as high as 50.0% as that of those with a favorable score, 26.4%.

Would you consider a nulliparous patient at term with an unfavorable cervix as determined by Bishop score a candidate for elective induction? I would also be interested in your comments regarding the seeming reluctance toward the use of prostaglandin gel at least in the nulliparous patient with an unfavorable cervix. In the discussion of an article I presented at the Pacific Coast Obstetrical and Gynecological Society in 1986[1] one discussant reviewed the 11 articles presented before the Society since 1931 and noted the repeated emphasis of the cervical requisites for elective induction.

I will let the words of Dr. Robert Goodlin act as the devil's advocate by quoting his comments in his formal discussion of my article regarding the Food and Drug Administration statement warning against the use of oxytocin for elective induction. "I remember with fondness the days of elective inductions when the patient's labor was induced on Friday so that the husband could take care of the children on the weekend, the obstetrician would be relatively free of weekend deliveries, and everyone was happy. It now appears that these wonderful times are available to obstetricians and their patients in Portland (Pasadena). I am curious as to how the Food and Drug Administration regulations are avoided."

DR. EZRA DAVIDSON, Los Angeles, California. Why do you call the decision to have or not to have an elective induction an ethical question for the patient and her physician rather than a practical one?

DR. JAMES CAILLOUETTE, Pasadena, California. In medicine today, the term "managed care" is in vogue. Managed care is brought to our doorstep by the lawyers and MBAs at the demand of employers, the buyers of medical care plans. Not initiated by physicians, it is nevertheless the wave of our future. I believe that the trend in obstetrics will continue toward managed labor because traditional care for the normal woman in labor is no longer cost-effective. It is no longer feasible for individual physicians who have invested 12 years in training at a cost of hundreds of thousands of dollars to dedicate extended periods to observing one normal woman in labor. Managed labor for the normal obstetric patient is in the cards. Let us hope that it is the obstetricians who deal the hand.

DR. CLYDE VON DER AHE, Los Angeles, California. Elective inductions were being done 50 years ago. In 1943, when I was an intern at Saint Vincent's Hospital in Los Angeles, Dr. B.J. Hanley, who was to be President of this Society, would bring in for induction of labor five to seven women on most Wednesday and Saturday mornings. He would strip and then rupture the membranes and then he would use high doses of barbiturates and scopolamine followed by drip ether anesthesia. The cesarean section rate was very low. Around 6 or 7 PM it was interesting to watch the husbands who had arrived together in the morning saying to each other, "Well, what did you get?" "I have a girl." "I have a boy."

DR. MACER (Closing). Dr. Fearl, a patient admitted for induction of labor with the diagnosis of fetal macrosomia should have been excluded from this study. However, some may have had induction for this indication and the physician did not mention the reason in the chart. As you noted, there were 33 patients in the induction group whose babies weighed >4000 gm versus 21 in the spontaneous labor group. I do not have information about how many of these large infants were delivered by cesarean section.

In this retrospective study, few obstetricians chose to use prostaglandin gel or suppositories. Although the numbers are small, it appears that its use might be advantageous. Six of the 13 patients with labor induced by prostaglandins had Bishop scores of ≤5, and there was only one cesarean section in this group.

Tubal sterilization and risk of subsequent hospital admission for menstrual disorders

Kirk K. Shy, MD, Andy Stergachis, PhD, Louis G. Grothaus, MS, Edward H. Wagner, MD, Julia Hecht, PhD, and Garnet Anderson, PhD

Seattle, Washington

OBJECTIVE: Our objective was to investigate tubal sterilization and subsequent hospitalization for menstrual disorders.

STUDY DESIGN: Automated discharge data were used in a population-based cohort study of 7253 women aged 20 to 49 years with tubal sterilization (1968 through 1983) at Group Health Cooperative of Puget Sound. Comparisons were with an age-matched cohort of 25,448 nonsterilized women and a nonmatched cohort of 5283 spouses of men with vasectomies.

RESULTS: In the sterilization cohort, 282 had hospitalization for menstrual disorders (curettage, $n = 191$; hysterectomy, $n = 66$; nonsurgical, $n = 25$). Risk of hospitalization for menstrual disorders was 2.4 times greater after tubal sterilization (95% confidence interval 2.0 to 2.9). This risk was 6.1 times greater for sterilized women aged 20 to 24 years (95% confidence interval 0.72 to 3.2). Compared with the risk for nonsterilized women whose spouses had a vasectomy, the risk was 1.6 times greater (95% confidence interval 1.3 to 2.1). Hospitalization for menstrual disorders was not more common after unipolar sterilization than after other methods, as might have been expected if the menstrual disorder was related to impaired uteroovarian circulation.

CONCLUSIONS: Tubal sterilization is associated with a greater risk of hospitalization for menstrual disorders. A biologic association is not supported by these results. (Am J Obstet Gynecol 1992;166: 1698-1706.)

Key words: Tubal sterilization, curettage, menorrhagia, metrorrhagia

Whether menstrual disorders are more common after tubal sterilization is controversial.[1] This issue is important because medical and surgical hospital admissions to manage menstrual disturbances[2] and tubal sterilization are both common.[3] We have previously reported an increased risk of hysterectomy after tubal sterilization.[4] Uterine bleeding was the indication for only 37% of the hysterectomies among the sterilized women in that report, and hospitalizations for curettage or other treatments for menstrual disorders were not considered. To clarify the relationship between tubal sterilization and first hospitalization for a menstrual disorder, we performed a large cohort study at Group Health Cooperative of Puget Sound, a nonprofit, consumer-governed, health maintenance organization located in western Washington. Characteristics of the Cooperative's population are similar to those of the rest of the community,[5] and this site offered the additional advantage of a population-based, automated data base for the over one million persons who have ever been enrolled in the Cooperative. These data enabled us to avoid the problems of other studies that were not population-based, had limited follow-up, or lacked an independent, nonsterilized comparison group.

Material and methods

Sterilized and nonsterilized women were eligible for study at Group Health Cooperative if they were 20 to 49 years of age between 1968 and 1983. Sterilized women were identified from surgical log books (1968-1971) and from automated hospital discharge data from the Commission on Hospital Professional Activities Study (1972-1984). Methods of sterilization were classified as postpartum (all by partial tubal resection), bipolar fulguration, unipolar fulguration, and other interval techniques (primarily isthmic tubal resection or fimbriectomy). During the period of this study, 16% of the sterilized women at Group Health Cooperative had postpartum sterilizations, 36% had bipolar techniques, 20% had unipolar techniques, and 27% had other interval techniques. Women were excluded if they

has been hospitalized for a primary or secondary diagnosis of menstrual disorder at Group Health Cooperative before the reference date. The reference date was the date of sterilization for the sterilized woman, and that date was also the reference date for the nonsterilized women matched to her. Nonsterilized women were excluded if they had a hysterectomy at Group Health Cooperative before their reference date or if they were not enrolled at the Cooperative as of their reference date. A hospitalization for menstrual disorder was included if it was the first hospitalization that had a medical record code for menorrhagia, metrorrhagia, hypermenorrhea, or dysmenorrhea. Ninety-three percent of hospitalizations for menstrual disorders were related to excessive or irregular bleeding, and 7% were related to dysmenorrhea alone.

Our analysis on the risk of hospitalization for menstrual disorder after tubal sterilization was based on two principal comparisons. The first comparison from the general population of Group Health Cooperative enrollees was between all eligible women who had a tubal sterilization ($n = 7253$) and a matched comparison group of nonsterilized women ($n = 25,448$). These comparison groups are to be referred to as the sterilized and general population cohorts, respectively; and the comparison involving these two cohorts is referred to as the population comparison. The second comparison was not matched, and it concerned only women who had a spouse enrolled in Group Health Cooperative. In this second comparison, married sterilized women ($n = 4057$) were compared with nonsterilized women ($n = 5283$) whose husbands had a vasectomy at Group Health Cooperative between 1968 and 1983. These comparison groups are referred to as the sterilized spouses and vasectomy spouses cohorts, respectively; and the comparison involving these latter two cohorts is referred to as the spouses' comparison. (The 4057 sterilized spouses are a subset of the 7253 women who were sterilized at Group Health Cooperative during the period of this study.) The spouses' comparison was included because in this comparison the couples had all chosen to have no further children. Whether childbearing is ended may be related to decisions regarding hospitalization for menstrual disorders, particularly those involving a hysterectomy.

Follow-up time began 1 year after the sterilization (or a corresponding reference date for the nonsterilized cohorts) and continued until first hospitalization for menstrual disorder, disenrollment from Group Health Cooperative, hysterectomy, or Dec. 31, 1984, the end of the study period. Hospitalizations during the first year after sterilization (or reference date) were excluded because routine preoperative and postoperative evaluation could have resulted in increased opportunity for diagnosis and treatment of menstrual disorders among sterilized women soon after the procedure. This detection bias would have increased estimates of the risk for menstrual disorders soon after sterilization.

Population comparison. Because data on factors such as gravidity and prior contraception were not contained in our automated data base, it was not suitable for assessment of confounding. Although these data would have been available from a manual review of all the hospital medical records, this was not feasible given the large number of women in the population comparison (>30,000 women). We considered medical record review of a lesser number of women from a random sample of each cohort or within the context of a case-control study. To achieve adequate statistical power, both of these approaches would also have required review of an inordinate number of medical records.[6] This would have been true for a cohort study of a random sample of subjects because the outcome (hospitalization for menstrual disorders) was rare (2%). Similarly, for a case-control study the exposure (tubal sterilization) was uncommon (10%) among women at Group Health Cooperative.

Therefore a more efficient two-stage, matched cohort design was used.[7, 8] The first stage of this cohort design is characterized by matching sterilized (exposed) and nonsterilized (nonexposed) subjects on factors available in an automated data base. Our matching was based on age (within 2 years) at sterilization (or reference date), and duration (within 1 year) of enrollment at Group Health Cooperative before sterilization (or reference date) (Table I). A 4:1 matching ratio was achieved for 86% of the sterilized cohort. For 10% of the sterilized cohort the matching ratio was 3:1, and for 4% the matching ratio was 2:1.

The second stage had a nested design that involved data abstraction from the medical records of a subgroup of these matched sets. Sets without an outcome (i.e., subsequent hospitalization for a menstrual disorder) were not included because these sets would not alter estimates of the relative risk.[8] One nonsterilized woman was selected at random from each set; thus matched sets became matched pairs, each containing one sterilized and one nonsterilized woman. All such pairs with at least one woman who was hospitalized for menstrual disorders were then identified with automated data. Because there were more pairs with hospitalization for menstrual disorders than needed to achieve statistical power to detect a relative risk of 2.0, 64 pairs (64 women from the sterilized cohort and 64 women from the general population cohort) were randomly selected for chart abstraction and data collection in the second stage of this comparison.

Medical record abstraction was done by two people. One reviewed the chart and verified the sterilization

Table I. Age and duration of Group Health Cooperative membership at sterilization or reference date, according to sterilization status

Age at sterilization/reference date (yr)	*Category of women*			
	All sterilized (n = 7253) (%)	*No sterilization (n = 25,448) (%)*	*Sterilized with spouses (n = 4057) (%)*	*Nonsterilized with sterilized spouses (n = 5283) (%)*
20-29	29	30	29	34
30-34	36	34	38	37
35-39	24	23	23	19
40-44	9	11	9	8
45-49	1	2	2	3
TOTALS	100	100	100	100
Mean of duration (yr) Group Health Cooperative membership at sterilization or reference date	5.97	5.96	5.95	5.47

status. A second person (blinded as to sterilization status) noted the presence (as of the sterilization or reference date) of several potentially confounding variables including married/living with (yes, no), gravidity, parity, history of menstrual disorder (yes, no), and contraceptive method (oral contraceptives, intrauterine device, other) in use at 6 months before the sterilization or reference date.

Spouses' comparison. Our second principal comparison (spouses' comparison) had a first stage in which we used a nonmatched cohort design to compare married, sterilized women to the wives of men who had vasectomies between 1968 and 1983. Men with vasectomies were identified from pathology logs that indicated a specimen from the vas deferens. Spouses were identified from automated enrollment data.

In the second stage of the spouses' comparison, we performed a nested, case-control study with data based on medical records to obtain relative risk estimates adjusted for the same potentially confounding variables as in the population comparison. Because the number of sterilized spouses and vasectomy spouses were similar, the case-control design had maximum efficiency for this task. Simple random samples of 105 cases of hospitalization for menstrual disorders and 205 controls not hospitalized for menstrual disorders were selected without regard to sterilization status.

Statistical analysis. For analyses involving the population comparison, the Cox proportional hazards model[9] was used to obtain estimates of the relative risk of hospitalization for menstrual disorders associated with sterilization. This analysis was stratified on the matched sets used in the design (thus controlling for age and duration of enrollment at Group Health Cooperative before sterilization or reference date). For the spouses' comparison, an unmatched Cox proportional hazards model was used to obtain estimates of the relative risk, controlling only for age and duration of enrollment. In the nested studies adjustment for the additional potential confounding variables listed above (e.g., gravidity) was by conditional logistic regression in the population comparison and by unconditional logistic regression in the spouses' comparison. These potentially confounding variables were chosen because they were considered to have an influence on a woman's inherent risk of hospitalization for menstrual disorders. All p values were based on maximal probability likelihood ratio tests. Extensions of the primary Cox logistic regression models were used to test for effect modification with age and duration of follow-up.

Results

Sterilized women had higher rates of hospitalization for menstrual disorders than did general population women: 955 versus 367 (per 100,000 person years), respectively ($p < 0.001$). The corresponding relative risk (unadjusted except for matching variables) of hospitalization for menstrual disorders associated with sterilization was 2.4 (95% confidence interval 2.0-2.9, $p < 0.001$) (Table II). This risk did not vary with duration of follow-up. The effect of sterilization depended greatly on age ($p < 0.005$). Among women who were sterilized at age 20 to 29 years, the risk of hospitalization for menstrual disorders was more than five times greater among sterilized women compared with nonsterilized women. The risk of hospitalization for menstrual disorders was 1.3 to 2.9 times greater for women sterilized in other age decades (Table III). When medical record data from the second phase of the population comparison were used to also control

45-49	7	616	13	2,409	1.7 (0.7-21.2)
p†					<0.005

*Reference date and duration of Group Health Cooperative membership at reference date were controlled for. Numbers in parentheses are 95% confidence intervals.

†*p* Value refers to likelihood that all relative risks are the same across age groups.

for potentially confounding factors (marital status, history of prior menstrual disorders, gravidity, and prior contraception) the adjusted risk of hospitalization for menstrual disorders declined to 1.5 (95% confidence interval 0.72 to 3.2 $p > 0.20$) and was no longer statistically significant (Table IV). Gravidity was strongly related to hospitalization for a menstrual disorder ($p < 0.01$).

Sterilization procedures were analyzed individually. With unipolar procedures the risk of hospitalization for menstrual disorders increased 2.1 times (95% confidence interval 1.4 to 3.2), with bipolar procedures the risk increased 2.3 times (95% confidence interval 1.5 to 3.4), with other interval procedures the risk increased 3.8 times (95% confidence interval 2.8 to 5.1), and with postpartum methods the risk increased 2.6 times (95% confidence interval 1.6 to 4.1). However, differences between sterilization procedures in risk of hospitalization for menstrual disorders were not statistically significant ($p > 0.25$).

At the first hospitalization for menstrual disorders, the ratio of women submitted directly (i.e., without preceding curettage) to hysterectomy was 1.6 times greater in the tubal sterilization cohort compared with the nonsterilized, general population cohort (Fig. 1). Among women who were hospitalized for menstrual disorders, in the sterilized cohort 68% (191/282) had curettage as initial treatment versus 75% (255/340) from the general population cohort. When all hospitalizations for menstrual disorders were considered (after the patient's first hospitalization), hysterectomy was eventually included in the treatment of 43% (121/282) of women from the sterilized cohort who were hospitalized for menstrual disorders compared with 38% (129/340) of nonsterilized women for the general population cohort.

In the spouses' comparison, sterilized spouses had higher rates of hospitalization for menstrual disorders than did vasectomy spouses: 1071 versus 816 (per 100,000 person years), respectively ($p < 0.001$). The corresponding relative risk associated with sterilization was 1.6 (95% confidence interval 1.3 to 2.1, $p < 0.001$)

*This was a matched (conditional) logistic regression model based on analysis of 64 matched pairs, each containing one sterilized woman and one nonsterilized woman. One woman in each pair was hospitalized for menstrual disorders and one woman was not. (See text for explanation of sampling procedures.)

†Matching variables were age, reference date (1977 to 1981/1982 to 1983), and duration (1-year intervals) of Group Health Cooperative membership at sterilization or reference date.

‡*p* Value for exposure tests a difference in risk across categories (based on deviance test).

(Table II). The increase in hospitalizations for menstrual disorders did not vary substantially with age category or duration of follow-up. After adjustment for potentially confounding factors (history of prior menstrual disorder, gravidity, and prior contraception) in the nested case-control study, women with their first hospitalization for menstrual disorder were 2.0 times (95% confidence interval 1.2 to 3.4, $p < 0.01$) more likely to have been sterilized (Table V).

At first hospitalization for menstrual disorders in the spouses' comparison, the ratio of women submitted directly to hysterectomy was 1.5 times greater in sterilized spouses' cohort compared with vasectomy spouses (Fig. 2). Among women who were hospitalized for menstrual disorders, 67% (102/153) of sterilized spouses had curettage as initial treatment versus 79% (129/164) of vasectomy spouses. Hysterectomy was included in the eventual treatment of 59% (91/153) of sterilized spouses with hospitalization for menstrual disorder compared with 45% (73/164) of vasectomy spouses.

In the multivariate models for both the general population comparison and the sterilized spouse comparison, adjustment for potential confounders indicated an inverse relationship between age and risk of hospitalization for menstrual disorders. Regardless of the cohort, sterilized women between 20 and 29 years of age had the greatest risk for hospitalization for menstrual disorder.

Comment

We found that sterilized women are at increased risk of subsequent hospitalization for menstrual disorders. The increased risk has at least three possible explanations. (1) Tubal destruction interferes with the uteroovarian blood flow and results in altered ovarian hormone production leading to menstrual irregularity.[10] (2) Women who elect tubal sterilization for contraception are inherently greater users of other elective gynecologic surgeries (e.g., curettage, hysterectomy). (3) After reproduction is no longer possible, physicians and their patients are more inclined to choose hysterectomy as management for menstrual disorders.[11]

Under the hypothesis that impaired uteroovarian circulation results in altered estrogen production and menstrual disturbance,[10] unipolar fulguration, which disrupts more of the mesosalpinx than other sterilization techniques,[12] would be expected to have a greater risk of menstrual disturbance than other sterilization methods. However, our results indicated that the risk of menstrual disturbance was lowest among women

‡Coded as continuous variable (i.e., 0, 1, 2, 3, etc.).

with unipolar sterilization compared with other sterilization methods. Thus on the basis of our data an increase in menstrual disturbance related to interference with the uterotubal circulation seems unlikely.

Our data were insufficient to determine patients' underlying likelihood (or preference) for elective surgery. Preference for elective gynecologic surgical treatment could prompt elective surgery (by tubal sterilization) for contraception and elective surgery (by curettage or hysterectomy) for treatment of menstrual disorders. Similarly, other women may have a preference for nonsurgical contraception and nonsurgical treatment of menstrual disorders. Because couples choosing permanent contraception by vasectomy (rather than by female sterilization) are relatively adverse to elective gynecologic surgery, preference for nonsurgical treatment would probably have had the greatest effect on the results from the spouses' comparison. In our results, the adjusted risk of hospitalization for menstrual disturbance after sterilization was only slightly greater in the spouses' comparison relative to the population comparison. Shain et al.[13] found that women whose husbands have undergone vasectomy are more likely than married women with tubal sterilization to be especially fearful of reproductive surgery.

Scott[11] suggested that because future pregnancy is not a consideration after tubal sterilization, patients and physicians are more likely to choose elective hysterectomy as treatment for gynecologic problems such as menstrual disorders. In our study, among women with their first hospitalization for menstrual disorders, 23% in the sterilized cohort and 24% in the sterilized spouses cohort were submitted directly to hysterectomy, versus 14% from the general population cohort and 16% from the vasectomy spouse cohort (Figs. 1 and 2). This practice difference is consistent with Scott[11] and suggests that patients' and physicians' views regarding the reduced need to preserve reproductive potential may have contributed to the increase in hospitalization for menstrual disorders we observed after tubal sterilization.

At least two sources of bias may have affected our

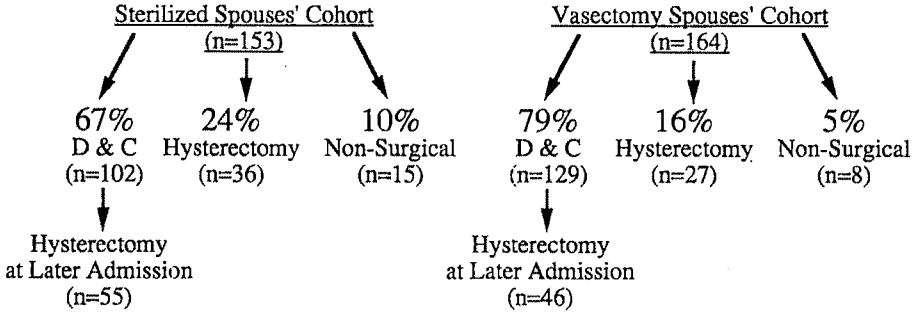

Fig. 2. Comparison of hospital management of menstrual disorders in the sterilized spouses.

results. First, because our data did not include the medical records of patients before enrollment in Group Health Cooperative, we probably included some women with prior tubal sterilizations in the nonsterilized cohorts. This bias (if present) would reduce the magnitude of our estimate of the risk of menstrual disorders. Alternatively, if women with prior hysterectomy were included in the nonsterilized cohorts, the risk of menstrual disorder would have been overestimated by our study. Second, because ours was not a randomized trial, we cannot exclude the possibility that residual confounding affected our results.

Most studies that compared menstrual events of sterilized and nonsterilized women suggest an increased risk of menstrual disorders after tubal sterilization.[14-17] These prior studies did not use hospitalization as an outcome, and they are troubled by limited follow-up time and the possibility of reporting bias because they are based on data from self-reported questionnaires.[14-17] In one study[17] that found an association between tubal sterilization and menstrual disorders, there was no significant difference between the two groups in self-reported physician visits for menstrual problems, and the increase occurred chiefly among women with preexisting menstrual disorders. Women with prior hospitalization for menstrual disorders were excluded from our study.

Because the outcome of our study was hospitalization, it is doubtful that our data can be applied to lesser changes in menstruation that do not warrant hospitalization. Nonetheless, studies[18, 19] of reported menstrual flow before and after sterilization are consistent with our findings that do not suggest a definite effect of the sterilization procedure itself. In the single study[20] that actually measured menstrual blood, no difference was found before and after tubal sterilization.

In summary, a direct risk of severe menstrual disorders resulting from tubal sterilization has little substantial support in our data. Increased tubal destruction associated with unipolar sterilization was not associated with increased risk for hospitalization for menstrual disorders. The increase in risk we observed was subject to bias resulting from women's underlying preference for, or against, elective surgical care. Direct submission to hysterectomy (rather than curettage or medical treatment) for a larger proportion of women hospitalized for menstrual disorders after tubal sterilization suggested physician (or patient) preference for hospitalization and hysterectomy (vs nonsurgical treatment) when maintenance of reproductive potential was no longer an issue in the treatment of menstrual disorders. We conclude that, although sterilized women are hospitalized more frequently for menstrual disorders, this finding may be explained by factors other than a biologic effect of the sterilization procedure itself.

Discussion

Dr. Robert Israel, Los Angeles, California. In 1951 Williams et al.[1] from Vanderbilt University published the first article on the possible relationship between tubal sterilization and subsequent abnormal uterine bleeding. They reported on the incidence of abnormal uterine bleeding in 200 women who had undergone prior tubal ligation compared with a group of nonsterilized women. Although the incidence of subsequent menorrhagia in the sterilized patients was similar to that in a randomly selected control group of hospitalized gynecology patients, the authors concluded that somehow women who have had a tubal sterilization later have a higher percentage of abnormal bleeding than would be expected "in the general female population." They concluded that, "in view of the very low mortality and morbidity resulting from simple hysterectomy in the absence of distortion of pelvic anatomy," hysterectomy rather than tubal sterilization should be considered "in those individuals with chronic or progressive diseases warranting destruction of their reproductive function. Procedures short of hysterectomy preserve only the menstrual function of the uterus and leave an organ that is, as far as is known, not only worthless but potentially dangerous." The study was retrospective, lacked appropriate matched controls, and ignored any preexisting menstrual disturbances in the sterilized women but did use life-table analysis. As you have just heard from Dr. Shy and the Seattle group, in the intervening 40 years we have become more statistically correct and much more circumspect in our conclusions.

Irregular cycles, menometrorrhagia, and dysmenorrhea occurring after tubal sterilization have been espoused as the leading representatives of the dreaded "posttubal syndrome." However, in spite of the 40 years from Williams to Shy, the question of whether tubal sterilization increases the risk of subsequent menstrual disturbances remains unsolved. The failure to definitively answer this question revolves around many confounding factors: (1) Obtaining an accurate, long-term, prior menstrual blood flow and cycle regularity history from patients is subject to significant recall bias; (2) discontinuing oral contraceptives coincident with the surgery may be the culprit in many instances rather than the operation itself; (3) many women will experience menstrual disturbances over time irrespective of whether a tubal sterilization was performed. It is becoming apparent, from the myriad number of studies that have attempted to look at the "posttubal syndrome," that if menstrual disturbances occur after tubal sterilization, they may take quite a while to develop and are more likely to occur in women who had abnormal presterilization menstrual histories. In addition to long-term, post-tubal-sterilization follow-up studies that include office or clinic visits for abnormal uterine bleeding and hospital admissions, there is a definite need for studies in which women have both presterilization and poststerilization hormonal determinations carried out to see if disturbances occur that may affect subsequent ovulatory function.

As with the Seattle group's earlier article,[2] this effort is well done, well written, statistically overwhelming, and provocatively appealing in its conclusions. First, women who elect tubal sterilization would be more likely to choose surgical treatment rather than medical therapy for any subsequent menstrual disorders. Second, these previously sterilized women, and their doctors, are more inclined to select hysterectomy for definitive relief.

Finally, I would like to compliment the authors for their honesty in clearly delineating the key deficiencies in the study. The failure of the automated data base to contain factors such as gravidity and prior contraception did eliminate an important area, the assessment of confounding variables. As they noted, with the nonrandomized nature of the study they could not exclude the possibility that the absent residual confounders adversely affected the overall results. In the 40 years that have passed since the Vanderbilt article, it is obvious that our research has become more sophisticated and our statistical designs more discriminating. With the passage of time and the improvement of scientific methods, these trends might have been expected. What might not have been anticipated is what Shy et al. have demonstrated so beautifully today—that even a negative study can be presented with unassuming integrity without resorting to the hyperbolic conclusions of the 1951 article.

DR. DUNCAN R. NEILSON, Portland, Oregon. Dr. Shy, oral contraceptives reduce the frequency of menstrual abnormalities. How many patients in the control group were taking oral contraceptives? Did you compare the poststerilization patients with controls not using oral contraceptives?

DR. SHY (Closing). Dr. Neilson, contraceptive histories are complex. We could have controlled for the contraceptive method in use just before the sterilization procedure. We chose, however, to control for the contraceptive method in use 6 months before sterilization because that seemed more relevant. In the analysis, when we stratified for contraceptive method used before sterilization, there was no modification in the conclusions.

Early amniocentesis: Outcome, risks, and technical problems at ≤12.8 weeks

Frederick W. Hanson, MD, Frances Tennant, PhD, Stacy Hune, MS, and Karen Brookhyser, MS

Davis, California

OBJECTIVE: It is the purpose of this report to evaluate our experience with amniocentesis at ≤12 weeks' gestation.

STUDY DESIGN: Medical records of 936 patients at ≤12.8 weeks' gestation undergoing genetic amniocentesis between Oct. 1, 1986, and June 30, 1990, were evaluated for gestational age, indication, frequency of needle insertion, amniocentesis complications, and pregnancy outcome.

RESULTS: There were seven miscarriages within 2 weeks of amniocentesis (0.7%), 21 miscarriages before 28 weeks (2.2%), and four stillbirths or neonatal deaths (0.4%), resulting in a total postprocedural loss rate of 3.4%. There were 26 chromosomally abnormal fetuses (2.8%). The spontaneous abortion rate in ultrasonographically normal pregnancies at <14 weeks, not undergoing amniocentesis, has been estimated at 2.1% to 3.2%.

CONCLUSION: Amniocentesis at 12 weeks is a viable option for patients desiring earlier prenatal genetic diagnostic information. (Am J Obstet Gynecol 1992; 166:1707-11.)

Key words: Early amniocentesis, miscarriage, amniotic fluid leakage

The prenatal diagnosis of chromosomal and biochemical abnormalities and neural tube defects is now a routine part of obstetric management. We can now offer patients a spectrum of diagnostic procedures commencing at 8 weeks' gestation including chorionic villus sampling, early amniocentesis, and standard amniocentesis.

Our first report concerning early amniocentesis appeared in 1987[1] and outlined our outcome, risk, and technical problem experience. This was followed by a second report, presented in 1989 and published in 1990,[2] that included continuous ultrasonographic guidance as a routine procedure for early amniocentesis. This report was criticized for a paucity of procedures performed at ≤12 weeks, with a recommendation for the publication of such data in the future to address that deficiency.

It is the purpose of this report to evaluate our experience with amniocentesis at ≤12 weeks.

Methods

The University of California, Davis prenatal diagnosis program has been previously described.[1-3] Since the inception of the program in 1976, >20,000 amniocentesis procedures have been performed, with more than 3000 of them before 15 weeks' gestation. The majority of these procedures have been performed by F.W.H. During the period of time covered by this report (Oct. 1, 1986, to June 30, 1990) 8165 amniocentesis procedures were performed. Each year 18% to 26% of the total was performed because of abnormalities of maternal serum α-fetoprotein levels detected as part of the California Maternal Serum Alpha-Fetoprotein Screening Program.

The data were evaluated for amniocentesis indication, gestational age at the time of amniocentesis, frequency of needle insertion, amniocentesis complications, and pregnancy outcome. For comparison with previously published studies, pregnancy loss data were divided into the following categories: ≤2 weeks after amniocentesis, ≤28 weeks' gestation (miscarriage); ≥28 weeks' gestation (stillbirth), and neonatal death (within 1 week of birth). Loss data were further evaluated as to possible or probable causal relationships to amniocentesis.

The amniocentesis technique used in our program has been previously described.[1-3] Continuous ultrasonographic monitoring has been routinely used since Oct. 1, 1986, to guide needle placement and monitor fetal movement during amniocentesis. We use an ATL Ultramark 4 ultrasonography machine (Advanced Technology Laboratories, Bothell, Wash.) for this purpose. A 22-gauge spinal needle is routinely used, with removal of approximately 1 ml of amniotic fluid (maxi-

*Weeks since last menstrual period ± 1 week.

mum 18 ml) for each week of gestational age, which is based on the measurement of fetal biparietal diameter.

Amniotic fluid is cultured with the in situ technique of Peakman.* Fifteen clones and five karyotypes were usually examined, analyzed, and reported. The experience of our cytogenetic laboratory in the culture of amniotic fluid from 10 to 14-week pregnancies has been reported.[4] The mean culture time is 8.8 days (SD 1.5 days).

Results

The demographic data of the study population were not different when compared with those published in our previous studies.[1-3] The indications for amniocentesis are seen in Table I.

A total of 8165 amniocenteses was performed during the study period, including those performed because of abnormal maternal serum α-fetoprotein levels. Only patients with viable singleton pregnancies were included in this study. All preamniocentesis fetal deaths and multiple gestations were excluded from this study. There were 936 amniocenteses (performed at ≤12.8 weeks since the last menstrual period) that met these criteria, and they represent 11.5% (936/8165) of the total. The patient distribution by gestational age (as determined by biparietal diameter) is demonstrated in Table II. With the exception of three patients in 1990, all amniocenteses were performed by the same operator.

*David Peakman and Associates Reproductive Genetics Center, P.C., Denver, Colo.

Table III. Frequency of needle insertion

No. of insertions	*Frequency*	*%*
1	852	96.9
2	26	3.0
3	1	0.1

Excludes 57 patients from Oct. 1, 1986, to Sept. 30, 1987.

Table IV. Complications within 2 weeks of early amniocentesis

Complication	*No. of patients*	*%*
None	914	97.6
Fluid leakage	10	1.1
Miscarriage <2 wk	7	0.7
Bleeding	4	0.4
Cramping	1	0.1

The frequency of needle insertion is demonstrated in Table III. A total of 96.9% (852/879) were successfully performed with a single needle insertion. In one patient a retap was done because of inadequate cell growth, and subsequently the pregnancy was lost.

The volume of amniotic fluid removed varied from 10 to 18 ml. We have previously shown that the volume of amniotic fluid removed does not appear to influence an adverse pregnancy outcome.[3]

Table IV shows the number of patients who had complications within 2 weeks of amniocentesis. Of all the patients 97.6% (914/936) did not experience problems. Seven patients or 0.7% (7/936) had an unanticipated pregnancy loss within 2 weeks of amniocentesis.

Ten patients (1.1% of the total) had amniotic fluid leakage of several days' duration after amniocentesis. The pregnancy outcomes for the 10 patients with amniotic fluid leakage are seen in Table V. Four patients representing 40% (4/10) of the total number experiencing leakage after amniocentesis lost the pregnancy, and six patients or 60% (6/10) experienced term deliveries.

Table V. Pregnancy outcome in patients with amniotic fluid leakage

Case No.	*Gestational age (wk)*	*Complications before amniocentesis*	*Pregnancy outcome*
1	12.5	None	Normal term vaginal delivery
2	12.5	None	Normal term vaginal delivery
3	12.5	Severe spotting and cramping	Fetal death ≤2 wk
4	12.8	None	Fetal death ≤2 wk
5	12.2	None	Normal term vaginal delivery
6	12.2	None	Fetal death ≤2 wk
7	12.2	None	Normal term vaginal delivery
8	12.5	None	Normal term vaginal delivery
9	12.5	None	Fetal death ≤2 wk
10	11.8	None	Normal term vaginal delivery

Pregnancy outcome for all patients included in this study is listed in Table VI. A total of 92.4% (865/936) of patients were delivered of a normal child. No patients were lost to follow-up.

Six patients (0.6%) were seen with a variety of abnormalities, such as cleft lip or palate, club foot, and hydrocephalus, that were not detected prenatally. These were of insufficient frequency to rate placement in individual categories. Unlike our previously published studies,[1-3] no patients with fetal death before amniocentesis were included in this study.

Twenty-six patients (26/936) or 2.8% had fetuses that were structurally or chormosomally abnormal and chose to terminate their pregnancies.

Thirty-two patients representing 3.4% (32/936) of the total experienced losses at some point after the amniocentesis. Seven (0.7%) of the total (7/936) experienced a loss within 2 weeks of amniocentesis. Twenty-one or 2.2% (21/936) experienced a loss between 2 and 28 weeks after amniocentesis. There were four or 0.6% (4/936) stillbirths or neonatal deaths.

Four of the seven patients with losses within 2 weeks of amniocentesis experienced amniotic fluid leakage. One of these patients had two prior spontaneous abortions and severe cramping and bleeding for 2 weeks before the amniocentesis. Retrospectively, amniocentesis probably should have been delayed in this patient. No other preamniocentesis factors were identified to account for these losses.

Evaluation of the losses occurring >2 weeks and <28 weeks (21 patients) revealed that 14 patients had one or more normal visits to their referring physicians before documentation of the loss. Other complicating factors such as omphalocele, diabetes, preamniocentesis bleeding, chromosomal mosaicism, or umbilical cord accident could also be identified in these patients. Seven patients did not have any plausible factor identified to indicate that the loss was not procedure related.

The overall loss rate of desired pregnancies in this study was 6.2% (58/936). This percentage represents a summation of those losses occurring after ammniocentesis (n = 28), stillbirth or neonatal deaths (n = 4), and elective termination of abnormal pregnancies (n = 26).

Table VI. Pregnancy outcome for 936 patients undergoing amniocentesis at ≤12.8 weeks

Outcome	*No. of patients*	*%*
Normal fetus	865	92.4
Fetus abnormal—pregnancy terminated	26	2.8
Miscarriage ≤28 weeks' gestation	21	2.2
Premature delivery, <35 weeks' gestation	4	0.4
Miscarriage at ≤2 weeks after amniocentesis	7	0.7
Stillbirth or neonatal death	4	0.4
Abnormal child not detected prenatally	6	0.6
Small-for-gestational-age infant	1	0.1
Other	2	0.2

Comment

A variety of prenatal diagnostic procedures, including traditional amniocentesis (15 to 18 weeks), earlier amniocentesis (<15 weeks), and chorionic villus sampling (8 to 12 weeks), are now available to obstetric patients. Numerous reports have been generated with regard to the safety and hazards of these procedures.[1-3, 5-9] Fetal loss rates for amniocentesis have ranged from a low of 0.3%[9] to 2.8%.[5] A combined loss rate for desired pregnancy (spontaneous and missed abortion, termination of abnormal pregnancy, stillbirth, and neonatal deaths) of 7.2% has been reported for chorionic villus sampling.[10] Their amniocentesis

control group had a 5.7% loss rate. Adjustment of data led to the conclusion that a 0.8% difference in loss rate existed for the two groups and favored amniocentesis.
